

Bequeathed to the  
Department of Applied Chemistry  
University of Toronto

by the late

Harry Goulding Akers, B. A. Sc.,

a graduate of the

Faculty of Applied Science and Engineering, University  
of Toronto, in the Class of 1909.

Died at Yorktown, Virginia, April 21, 1917.

Digitized by the Internet Archive  
in 2011 with funding from  
University of Toronto

INDEX OF VOL. III. — 1884.

## INDEX OF AUTHORS' NAMES.

	PAGE		PAGE
Abbott, Decomposition of Blasting Gelatine.....	617	Badische Anilin u. Sodafabrik, Auramine.....	473
Abel, Flashing Point of Petroleum.....	161	Artificial Indigo.....	105
Abel, F. A., and Deering, W., Carbon in Steel.....	178	Baeker, W., Gas Producer (illus.).....	473
Abel, Sir F., and Redwood, B., Petroleum Testing in the Tropics.....	318	Baeyer, Condensation of Aldehydes with Phenols.....	252
Abel, Sir F. A., Discussion on Uniform Methods of Analysis.....	7	Rosolic Acid.....	371
Abel, C. D., Ammonia Soda Process.....	239	Baeyer, Ad., and Becker, P., Paranitrobenzaldehyde and Acetone.....	26
Abel and Tidy, Oils for Creosoting Timber.....	621	and Acetone.....	26
Action Ges. f. Anil. Fab. (Berlin), Base from Action of Aldehyde on Aniline Hydrochloride.....	211	Orthonitrobenzaldehyde and Aldehyde.....	27
Blue from Dimethylaniline.....	515	Baird, Coal Cutting Machine.....	371
Brown Azo Colours from Chrysoidines.....	28	Balanche, Steam Manganese Brown.....	235
Employment of Acid Alkaline Sulphates in preparation of Organic Compounds.....	105	Balard, Specific Gravity of Bromine.....	66
Action, Ges. Georg Egestorff's Salzwerke, Separation of Iron from Solutions containing Zinc.....	111	Balzberg, C. v., The Salt Industry (illus.).....	170
Addie, James.....	159	Bang, T. A. F., Manufacture of Glycerine.....	149
Addie, John, Ammonia Salts from Combustible Gases.....	159	Bang, J. A. F., and Castro, J. de, Treatment of Fats for Soap Making.....	31
Aders, J., Rectifier for Benzene.....	73	Banhard, E. O., Separation of Glycerine from Fats.....	112
Aitken, H., Coke Oven (illus.).....	601	<i>Banque Industrielle de Belgique</i> , Ulin Brown.....	106
Treatment of Coal in Coke Making, etc.,.....	138	Barbe, F., Non-deliquescent Phosphate of Lime.....	411
Akitt, T., See Mills and Akitt.....	366	Barbier, L., Manufacture of Glucose.....	375
Albert, N., Anti-incrustant Powder.....	368	Barbieri, J., See Schulze and Barbieri.....	323
Alexejew, P., Indigo Blue.....	111	Barker, Discussion on Oxidation of Cellulose.....	294
Allary, E., Saccharimeter.....	527	Barrett, Method of Reading Barometer.....	88
Allen, A. H., Discussion on Uniform Methods of Analysis.....	4	Barth and Schreder, Action of Sodium Hydrate on Resorcinol.....	476
Discussion on Estimation of Oils.....	367	Baubigny, Action of Sodium on Camphor.....	190
Discussion on Tars from Coke Ovens.....	65	Baubigny, H., Oxidation of Chromium Oxide.....	457
Stability of Hypobromite Solution and its Use for Titration of Oils, &c.....	65	Baum, H., Aniline and Acetic Anhydride Derivatives.....	214
Zinc in Spanish Iron Ore.....	5	α-Naphthol Derivatives.....	213
Allen, C. M., Extract of Mangrove Bark for Tanning.....	450	Beta-Naphtholdisulphonic Acid.....	211
Allen, J., Refined Sugar.....	113	Baum, See Schleper and Baum.....	55
Allen, J. F., Discussion on Vapours Injurious to Vegetation.....	312	Baumert, G., Residues of Spirit Manufacture as Cattle Food.....	578
Allen, Discussion on Methods of Sampling.....	311	Bäuml, A., Maize Malt.....	528
Allhusen, A., Discussion on Address to Newcastle Section.....	501	Baur, R., Analysis of Carbonates (illus.).....	650
Machinery for Salt Cake.....	502	Rapid Estimation of Available Chlorine.....	239
Allihn, F., Action of Dilute Hydrochloric Acid on Starch.....	323	Baynes, R., and Fearenside, J., Purification of Petroleum.....	438
Amthor, C., Development of Cherries and Currants.....	184	Bazalgette, C. N., Precipitation of Sewage.....	41
Andeer, J., Resorcin Blue.....	250	Beardmore, W., and Cherrie, J. M., Manufacture of Steel.....	524
Anderson, W., Purifying Water.....	529	Beaumont, Diamond Drill.....	371
Andes, L. E., Wood Mortants.....	519	Bechamp, Fermentation.....	518
Andreae, B., Manufacture of Gas (illus.).....	556	Bechi, G. v., Constitution of Phthalyl Chloride.....	211
Andresen, Indophenols.....	236	Becker, H., Concentration of Sulphuric Acid.....	355
Angerstein, H., Manufacture of Sulphuric Anhydride, (illus.).....	481	Becker, P., See Baeyer and Becker.....	26
Sampling Instrument (illus.).....	650	Beckurts, H., Detection of Acetic Acid in Formic Acid.....	580
Anschuetz, R., Acridine Pierate.....	234	Behrend, Effect of Warmth on Yeast.....	188
Employment of Anhydrous Oxalic Acid in the Formation of Condensation Products.....	139	Beilby, G., Production of Ammonia from Nitrogen of Minerals (illus.).....	216
Archbutt, L., Free Acids in Fats.....	511	Beilstein, F., Examination of Petroleum.....	161
Arfvedson, Action of Lithia on Platinum.....	301	Beilstein, Flashing Point of Petroleum (illus.).....	235
Arlow, H., Manufacture of Matches (illus.).....	378	Recovery of Benzenes from Sulphonic Acids.....	371
Armstrong, H. E., By-products of Manufacture of Oil-Gas (illus.).....	162	Beilstein and Geitner, Nitration of Benzyl Chloride.....	211
Armstrong, Discussion on Illuminating Power of Coal Gas.....	286	Bell, C. E., Density of Coke.....	612
Armstrong, H. E., Discussion on Uniform Methods of Analysis.....	3	Bell, J., Carter, Discussion on Standard Methods of Sampling, etc.,.....	213
Armstrong, Estimation of Oils and Fats.....	65	Bell, J. C., Manufacture of White Lead.....	218
Armstrong, H. E., and Miller, A. K., Recovery of Benzenes from Sulphonic Acids.....	371	Bell, J. C., Vote of thanks to President at Annual Meeting.....	393
Armstrong and Miller, Paraxylene.....	351	Bell, R. G., Preserving Beer, etc.,.....	327, 423
Armstrong, Sir W., Production of Cold by Expansion of Air.....	358	Bell, T. L. G., Alumina Compounds.....	173
Arnaud and Padé, Estimation of Nitrates.....	576	Bellman, See Ost and Bellman.....	329
Aspinwall, J. L., See Shepherd and Aspinwall.....	30	Beilmer, H., Boiler Incrustation Preventives.....	568
Athenstaedt, H., Detection of Tartaric Acid in Citric Acid.....	443	Belohoubek, Action of Water on Tinned and Sulphurised Lead Pipes.....	493
Athenstaedt, J., Preparations of Acetate of Alumina.....	108	Bender, F., See Berntsen and Bender.....	24, 161
Athenstaedt, Benzene, &c., from Wood Tar.....	466	Benedikt, Diresorcin.....	628
Aubin, E., Estimation of Phosphoric Acid.....	575	Benedikt, R., Colouring Matters of Plants.....	515
Aubrey, Nitrogen in Barley.....	577	Benedikt, R., and Julius P., Diresorcinol and Diresorcinaphthalen.....	476
Anshuetz, Chrysaniline.....	212	Benker and Lasne, Sulphuric Acid Manufacture.....	135
Avery, R. B., Arrangement for Burning Hydrocarbons.....	473	Bennett, J., See Walker and Bennett.....	473
		Bennett, R., See Lones, Vernon, etc.,.....	109
		Bérard, Carnauba Wax.....	418
		Bérard, Preparation of Hydrogen.....	496
		Bergholz, Kinoin.....	616
		Berthoud, E., Separation of Tin, Antimony, and Arsenic.....	341
		Bergreen, R., Separation of Non Saccharine Substances from Beet Juice.....	113

	PAGE		PAGE
Berkefeld. See Frank and Berkefeld	133	Brown, M. T. Cooling by Means of Air	363
Bernhardt. Estimation of Morphine	329	Brown, W., jun., and Gregg, H. Peat Fibre	424
Bernthsen, A. The Acridines	110	Brown and Heron. Maltose	400
Juglone	616	Bruckner. See Jacobsen and Bruckner	80
Methylene Blue	251, 411	Bruck, F. Coke Oven (illus.)	510
Violet from Diphenylamine	515	Bruck, Alizarin Blue	627
Bernthsen, A., and Bender, F. Acridine	24, 161	<i>Bruswick Maschinenbauanstalt.</i> Extraction of Sugar	571
Bernthsen and Bender. Phenylacridine	161	Bruntun. Tunnelling Machine	374
Bert, P. Action of Diastase on Starch	402	Brustlein. Action of Silicon on Steel	447
Bert, P., and Mignol. Peroxide of Hydrogen and Bacteria	515	Bryson, W. A. Production of Ammonia	223
Bertholot. Fixation of Nitrogen by Plants	185	Bucha. Haematoxylin and Brazilin	628
Nitrates in the Vegetable Kingdom	576	Buechner, M. Vegetable Wax	574
Berzelius. Sulphur Compounds of Sodium	413	Buechner. See Fittig and Buechner	409
Besthorn. Flavaniline	24	Buff. Bassia Fat	574
Besthorn, E., and Fischer, O. Flavaniline	27	Bull, H. C. Production of Gas	23, 408
Bethell. Treatment of Timber	622	Bull's Gaslight and Coke Co. Manufacture of Gas (illus.)	556
Bevan, E. J. See Cross and Bevan	205, 291	Bunsen. Estimation of Sulphurous Acid	197
Beveridge, J. Treatment of Antimony Ores	497	See Dupasquier and Bunsen	259
Beyer and Kegel. Dinitrophenolparasulphonic Acid	166	Bunte. Heat of Combustion of Various Fuels	232
Biedermann. Dibrom- $\alpha$ -Naphthol	238	Bunte, H. Production of Heating Gas	513
Biel, J. Russian Petroleum and Lamps	565	Bunte. See Schilling and Bunte	92
Bielenberg, J. Hydraulic Cements from Silicious Earths	110	Burg. See Liebermann and Burg	65, 166
Biggart. Standard Methods of Sampling, etc.	314	Burghardt, C. A. Condenser for Naphtha, etc.	157
Bindschedler, R. Coloring Matters of the Saffranine Group	27	Burnett. Treatment of Timber	622
Bindschedler. Dimethylphenylene Green	238	Burnham, W. Elastic Waterproof Compounds	113
Phenosaffranin	230	Burt. Croosoting Timber	625
Binnie, A. Gas from Fats, etc.	559	Burton, T. See Carnelly and Burton	470
Biot and Persoz. Action of Diastase on Starch	399	Butterfield, J. C. Manufacture of Antimony	180
Birnbaum. Nickel-plated Cooking Utensils	178	Calliburecs, P. System of Evaporation and Distillation	407
Bissell, S. Metallurgical Furnaces	418	Calm, A. Action of Aniline on Resorcinol and Quinol	161
Blake, E. C. T. Material for Insulators, etc.	490	Carey, E. Discussion on Methods of Sampling	341
Blanche. Metallic Sulphides as Mordants	166	Discussion on New Patent Law	11
Blas and Miest. Electrolytic Extraction of Metals	260	Carey. See Gaskell, Deacon and Co.	389
Blitz, R. Preparation of Fibre for Paper-making	190	Carey, E., and Hurter, F. Manufacture of Soda	481
Wood Pulp Manufacture	495	Carius. Strength of Solutions of Ammonia	124
Blockmann, R. Phenol-phthalein as an Indicator for Carbon Dioxide	456	Sulphur Monochloride	444
Blondin. See Broquette and Blondin	255	Carles, P. Estimation of Potassium Iodide	331
Blythe, F. C. Arseniate of Soda	173	Carnelly, T., and Burton, T. Pyrometer (illus.)	470
Boake and Co. Anhydrous Sulphurous Acid (illus.)	500	Carnot and Richard. Blue Crystals in Basic Slag from Jonef	180
Bock, J. Purification of Sewage	189	Caro, H. Colours obtained by Action of Phosgene Gas	319
Boehme, E. Cement	521	Caro. Extraction of Benzene from Coal Gas	432
The Welding of Iron	486	See Graebe and Caro	410, 441
Boehmcr. Action of Zinc Sulphate on Plants	417	Carpenter, W. L. Discussion on Porter-Clark Process	51
Estimation of Nitric Acid	379	Discussion on Illuminating Power of Coal Gas	286
Boettger, H. Polysulphides of Sodium	413, 414	Solidification of Fatty Oils (illus.)	200
Re-actions of Thionyl Chloride	414	Carpenter, R. F. Discussion on Cooper's Lime Process of Gas-making	15
Boettinger, C. Hemlock Pine Tannin	523	Carré. Production of Cold by Means of Ammonia	358
Digallie Acid	526	Carsten-Heogveeen, H. J. Manuring Moorland	185
Boettinger and Loewe. Tannins of Oak Bark	181	Carter, J. F. See Walker and Carter	320
Bogomoletz, I. Separation of Strontium and Calcium	153	Carves. Coke Ovens	506
Boillot. See Schonbein and Boillot	547	Casella, L. and Co. Indophenol	238
Boivin, J. E., and Loiseau, M. D. Extraction of Sugar from Molasses	188	Cassel, H. R. Electrolytic Extraction of Metals	322
Bonnet, P., and Cie. Brown Colours on Fabrics	412	Casson, Smith. Gas Furnaces	99
Bonte, L. Extractive Treatment of Hops	326	Castro, J. de. See Bang and Castro	34
Bornemann, E. Formation of Aromatic Aldehydes	410	Cavazzi, A. Ferric Sulphate for Detection of Iodides	331
Borowsky, B. Manufacture of Clear Amber Varnish (illus.)	34	Cerrutti-Sella. Dyeing, Bleaching, Washing, etc.	477
Bosshard. Estimation of Ammonia in Animal Fluids	497	Chance, Messrs. Concentration of Sulphuric Acid	355
Boston Asbestos Co. Asbestos	517	Changy, C. de. Depolarising Electrolytic Baths	32
Bottley. Cooper's Lime Process of Gas-making	13	Chapman, G. Extracting Ammonia from Gases	415
Bott, J. E. Production of Gas	108	Chatelier, H. le. Decomposition of Cement by Water	522
Boublouf, S. Behaviour of Coloured Fabrics to Water and Air	476	Chemin, J. C. O. Bleaching Ozokerit	163
Boulton, S. B. Antiseptic Treatment of Timber	622	<i>Chemische Fabrik zu Nienburg an der Wesel.</i> Alumina	61
Preserving Wood	572	Chenut, L. Coke Oven (illus.)	104
Bouquet, L. de. Bi- and Tricalcium Phosphates	526	Cherrie, J. M. See Beardsmore and Cherrie	521
Bourbonze. Soldering Aluminium	639	Cherry, C., sen. Treating Ores	572
Bourcart, R. Mineral Colours used in Calico Printing	254	Chesnaiss, A. F. New Substitute for Indigo	28
Printing Natural Indigo on Calico	55	Childs, C. R. Hardening Steel	611
Thickenings, etc., for Calico Printing	167	Christie. Discussion on Algin	302
The Dyeing Properties of Anthragallol	140	Chrystal. Standard Methods of Sampling, etc.	313
Bourdet. See Pelonze and Bourdet	574	Church and Owen. Cespitine	159
Boussingault. Mineral Fuels	159	Ciamician, G. L., and Silber, P. Blue Colour from Pyrrol	236
Nitrates in Soils	185	Ciamician and Silber. Action of Pyrrol on Ketones	439
Boutmy. Lead in Preserved Food	494	Cimbal. Culture of the Potato	419
Bowen, O. Gunpowder	330	Claisen. Benzaldehyde and Acetone	26
Bower, A. S., and Thorp, T. Regenerative Gas-burner	233	Clamer, F. J. Coating Sheet Metal with Lead	180
Bowen, S. B. Concentrating Sulphuric Acid	30	Claparède. By-product of Aurin	411
Boyd. Discussion on the Gases in the Leaden Chamber	230	Clark. Water-softening Process	51
Bramall, H. Progress in Mine Engineering	373	Clark, A. M. Manufacture of Glucose from Wood	645
Bramwell, F. Discussion on Filtration of Water	131	Clark. Chrome-tanned Leather	619
Bramwell, Sir F. Discussion on Uniform Methods of Analysis	8	Clark, J. Composition of Tobacco	554
Purification of Water	51	Clarke, W., and Tansley, H. J. Dyeing Mixed Fabrics	568
Brand. See Telford and Brand	128	Claudet, F. Extraction of Silver and Gold from Copper Matte	415
Brand, A. Steel Smelting	572	Claudian, G., and Vigreux, C. Production of Yeast	114
Brandt. The Greening of Aniline Blacks	209	Claus. Chrysophenol	161
Brandt, J. Production of Phosphates from Slags	115	Claus, C. F. Manufacture of Hydrate of Strontia, and Hydro-sulphide of Sodium	107
Breithaupt, T. A. Antiseptic	124	Silicate of Zinc	122
Extracting Essential Oils from Hops, etc.	376	Strontium Hydrate	521
Brelaz, G. L. See Pietet and Brelaz	495	Recovery of Sulphur	393
Breuer, O. Dyeing Mixed Silk and Cotton Goods in Two Colours	372	Sulphur from Sulphuretted Hydrogen and Alkali Waste	481, 485
Briem, H. Sugar Refining	527	Clemence, A. B. Carbon in Iron and Steel (illus.)	652
Briggs, J. Lime Kilns	145	Coad, T. Porous Pots and Plates for Batteries	414
Brin, L. Q., and A. Artificial Production of Ammonia	173	Cobenzl, A. See Schmitt and Cobenzl	453
British Association. Methods of Estimating Phosphoric Acid	4	Cobley, T. H. See Gard and Cobley	104
Broenner. Betanaphtholsulphonic Acids	214	Treatment of Straw, etc., for Pulp and Manure	328
Broquette and Blondin. Ultramarine Fixed with Albumen	255	Coez, E. L. P. Preparation of Tannic Extracts	182
Brown, Campbell. Soda Tests	64	Coez, G. C. Preparation of Tannic Extracts	182
Brown, J. Campbell. Discussion on Methods of Sampling	342	Cohn and Mendelsohn. Bacterial Growth	545
		Cohn, L. and Co. "Corrosiv" (Anti-incerustator)	368

	PAGE		PAGE
Coisne. Creosoted Timber	622	Dixon, J. Paper Manufacture	376
Coleman. Refrigerators for Waste Liquors	611	Dixon, R. Coke Ovens	101
Coleman, J. J. Methods of producing Cold (illus.)	337	Density of Coke	612
Comey, A. M. See Michael and Comey	230	Dobbie. Statistics of Chemical Society Abstracts	153
Condy, H. B. White Lead	416	Dobbs, C. J. Paving Blocks from Slag	417
Constam, E. J. See Goldschmidt and Constam	159	Doebner. Resorcinol-benzene	441
Cooper, W. J. Extraction of Ammonia from Coal-gas	107	Doebner, O., and Miller, W. v. Tetrahydroquinidine	246
Cornwinder. Suitability of Manures	262	Doebner and Miller. Yellow Colours from Cumidine	566
Cosack. Action of Zinc Sulphate on Plants	417	Dollfus, A. Treatment of Cassin	629
Couper, P., and Rae, M. Distillation of Coal, etc.	475	Dollfus, Miég and Co. Prussian Blue	255
Cove, J., and Sherwood, W. P. Waterproofing Leather	611	Colours fixed with Albumen	255
Cowan, A. B. Coke Manufacture	472	Domier. Discussion on Uniform Methods of Analysis	7
Cox, J. H., jun. Ammoniacal Liquor	158	Donald, W. J. A. Chromate Process of Tanning	615
Crafts. See Friedel and Crafts	160	Donath, E. Working of Sheet Tin	490
Crellin, C. Refining Paraffin	236	Donkin. Decomposition of Ammonia by Heat	157
Crepin. Creosoted Timber	622	Dougall, A. Density of Coke	612
Crespel Bros., and Martin. Phosphate of Lime used in Soda Manufacture	173	Dougall, C. Cooper's Lime Process of Gas-making	13
Cresswell. Discussion on Disposal of Sewage Sludge	50	Dowson, J. E. Manufacture of Gas	233
Cridland, F. E. J. Report on Sampling Phosphates	316	Dragendorff. Adulterations of Volatile Oils	571
Cripps, J., jun. Manufacture of Size from Leather Shavings	116	Dralle, Chr. Haematoxilin and Brasilin	242
Cross, C. F., and Bevan, E. J. Oxidation of Cellulose	206	Oxidation of Purpurin	242
Cross, J., and Wells, G. I. J. Extraction of Silver, Lead, etc., from Bluestone, etc.	111	Drevermann and Sostmann. Extraction of Sugar	323
Crum, W. Ageing Printed Calico	61	Drew, E. Extraction of Hydrocarbons from Coal and Shale Gas	438, 475
Crum. Oxidising Chamber for Printed Calico	168	Drewsen, V. See Baeyer and Drewsen	26, 27
Theory of Dyeing	292	Dreyfus. Discussion on Determination of Nylenes	80
Cuisinier, L. Manufacture of Maltose	189	Dubois, C. Anti-fouling Paint	181
Maltose	492	Dubrunfaut. Action of Diastase on Starch	399

Valuation of Tartrate of Lime	619		

## INDEX OF SUBJECTS.

	PAGE		PAGE
Aecnaphthalene, Phenol of.....	319	Amidoazobenzene.....	370
Acetate of Lime, Valuation of Commercial.....	211	Amidogene (An Explosive).....	190
Acetic Acid, Detection in Formic Acid.....	580	Amidovalerianic Acid in Lupinus.....	323
Ferment (illus.).....	406	Ammonia, Artificial Production of.....	173
Manufacture.....	639	From Coal.....	236
Solubility of Oils and Fats in.....	524, 641, 643	From Coal Gas.....	107
Aceto-acetic Ether combined with Phenyl-hydrazine.....	568	From Coke Ovens (illus.).....	104, 435, 510, 512
Acetone and Paranitrobenzaldehyde.....	16	From Coke Ovens, Earliest Methods of Obtaining (illus.).....	601
Acetylphenylamine.....	24	From Combustible Gases.....	159, 103
Acetylene in Coal Gas.....	272	Decomposition by Heat.....	157
Increased Production from Coal.....	138	Estimation in Animal Fluids.....	427
Acetylpentamethylparaleucaniline.....	249	From Furnace Gases.....	415
Achroodextrin.....	400	From Gases and Sewage (illus.).....	630
Acidity of Commercial Fats and Oils.....	540	From Producer Gas.....	474
Acid-proof Blocks for Filters.....	101	Production of Cold by Means of.....	357
Acids, Injury done to Plants by.....	341	Production from Nitrates.....	479
Acridine.....	161, 24	Production from Nitrogen of Minerals (illus.).....	216
Hydro.....	24	Pyridine in Commercial.....	318
Methyl.....	474, 21	Quantity taken up by Air from Solutions.....	124
Nitroso-compound.....	234	Rate of Solution of Copper in Aqueous.....	125
Phenyl.....	165	Recovery from Alcohol used for Extracting Sugar.....	114
Picrate.....	234	Strength of Aqueous Solution.....	124
Pyrogenous Formation of.....	471	Yield from Lined Coal.....	13
Acridines.....	410	Soda Process.....	259, 481, 486
Address to Glasgow and West of Scotland Section, Inaugural.....	149	Soda Process Liquors, Hydrochloric Acid from.....	255
Air, Action in Bleaching.....	207	Soda Process, Recovery of Chlorine.....	490
In Coal Gas.....	272	Soda Process, Utilisation of Liquors.....	387
Heater for Print-works (illus.).....	56	Sulphate Manufacture.....	158
Of London, Manchester and St. Helens, Acid in.....	103	Ammoniacal Liquor.....	123
Production of Cold by means of (illus.).....	357	Solutions, Treatment of.....	423
Albumen, Comparison of Living with Dead.....	186	Ammonium Chloride, Hydrochloric Acid from.....	279
Uses in Calico-printing.....	255	Chloride, Reaction with Sulphuric Acid.....	577
Alcohol, Beverages free from.....	578	Hydrate, Non-existence of.....	478
Detection in Volatile Oils.....	579	Hydroxide, Non-existence of.....	413
From Market Refuse.....	421	Reagent for.....	581
Presence in Commercial Benzene.....	80	Sulphocyanide.....	30
From Starch.....	397, 513	Sulphocyanide, Action on Plants.....	184
From Wood.....	615	Sulphate, Ammonia from.....	789
Still, Converting Ordinary into Continuous (illus.).....	34	Amyl Compounds as Sources of Standard Light.....	621
Alcoholic Liquors treated by Electricity.....	189	Amylene, Formation of a Terpene from.....	376
Aldehyde and Orthonitrobenzaldehyde.....	27	Amylnaphthalene.....	514
Aldehydes, Action on Phenols.....	250, 252, 253	Analysis, Drop Method of.....	496
Action of Phenols on Aromatic.....	371	With Small Quantities.....	533
Phenylhydrazine as a Reagent for.....	331	Discussion on Uniform Methods of.....	2
Preparation of Aromatic.....	410	And Testing, Committee on Methods of.....	394
Products of Aromatic Bases with.....	628	Uniform Methods of.....	210, 307, 315
Algin.....	297	Aniline, Action on Aceto-acetic Ether.....	319
Alginate Acid.....	500	Action on Resorcinol and Quinol.....	164
Alizarin Blue, History of.....	626	Black on Cotton Barks (illus.).....	257
Printing.....	477	Colours Fixed by Metallic Sulphides.....	166
Utilisation of Waste Liquors.....	165	Animal Nutrition, Value of Woody Fibre in.....	422
In Wool-dyeing.....	594	Annatto, Origin and Preparation of.....	476
Amido.....	627	Anthracite, Analysis of.....	159
Nitro.....	627	Anthragallol, Dyeing Properties of (illus.).....	110
Alkali Industry in Germany.....	630	Anthraquinoline, Synthesis.....	249
Furnaces, Revolving.....	107	Anthraquinone, Compounds.....	516
Proof Vessels.....	303	Constitution of.....	170
Trade of England.....	479	Etc. Plan for Treatment with Sulphuric Acid.....	29
Used for Extraction of Carbolic Acid, Recovery of.....	107	Synthesis of.....	247
Waste, Recovery of Sulphur.....	259, 550	Anti-fouling Paint for Ships, etc.....	614
Waste, Recovery of Sulphur from (illus.).....	483, 485	Anti-incrustant Powder and Solution.....	768
Waste, Treatment of.....	373, 393	Antimony, Arsenic and Tin, Separation of.....	331
Works, Advantages of Machinery in.....	607	Extraction from Ores.....	486
Alkalimetry, Titration Apparatus for.....	408	Manufacture.....	180
Alkaline Bisulphates, Employment of.....	105	Mordant.....	329
Carbonates, Manufacture from Chlorides.....	109	Ores, Treatment of, with Hydrochloric Acid.....	447
Hydrates, Manufacture from Chlorides.....	109	Separation from Arsenic.....	649
Hyposulphites, Manufacture.....	30	Smelting (illus.).....	176
Polysulphites.....	444	Antiseptic.....	424
Solutions, Purification of.....	107	Properties of Bichromate of Potash.....	578
Sulphites, Manufacture.....	108	Saponified Rosin Oil as an.....	644
Alloys, Manufacture of.....	641	Treatment of Timber (illus.).....	622
Metallic.....	110	Arable Land, Reduction of Nitrates in.....	185
Aluminium, Boring through Loose.....	106	Archil, Substitute for.....	516
Alpha-naphthol, Colour from.....	374	Area required for Sewage Irrigation.....	42
Alpha-naphtholmethyl Ether, Yellow Dye from.....	165	Aromatic Acids, Colours from.....	410
Al m Manufacture.....	173	Bases with Aldehydes, Condensation Products.....	628
Alumina as Causes of Reduction of Superphosphate.....	420	Compounds, Determination of Halogens in Side-chains.....	455
And Lime Glass.....	169	Para-Compounds, Introduction of Diazo-group.....	517
Sulphate, Rendering Presence of Iron Non-detrimental to.....	108	Arsenic, Antimony and Tin, Separation of.....	331
Aluminium Acetate, Preparations of.....	108	Copper Freed from.....	415
Manufacture.....	180	Detection.....	580
Manufacture by Electrolysis.....	32, 443, 486, 640	Determination in Commercial Native Copper.....	374
Soldering.....	639	In Glass as a Source of Error in Analysis.....	263
Sulphate, Detection of Free Sulphuric Acid in.....	258	Removal of, from Sulphuric Acid.....	255
Sulphocyanide free from Iron.....	30	Separation from Solutions.....	519
Amalgamating Machine for Gold Ore.....	421	Separation from Tin and Antimony.....	649
Amber Colouring.....	391	Zinc free from.....	486
Varnish Manufacture (illus.).....	34	Arsenical Compounds, Are they Injurious to Vegetable Life?.....	327

	PAGE		PAGE
Asbestos, Canadian and Italian	517	Bleaching and Printing, Chemistry of	206
Treatment of	108	Vessel for yarns (illus.)	629
Ascension Pipes, Cause of Stoppage in	160	Powder Chamber, Mechanical	390
Aseptol a new Antiseptic	530	Powder, Statistics of	180
Asphaltum, Analyses of	139	Blende, Furnaces for Roasting (illus.)	631, 632
Aspirator, Double (illus.)	368	Blood, Determination of Ammonia in	497
Astralin (Russian Mineral Oil)	181	As Manure	262
Auramine (Yellow Colour)	475, 517	Blue Colours from Amidoazo Bodies	28
Aurin, By-product of	141	Colouring Matters from Dimethylaniline	515
Auron	372	Colour from Diethylanilineazobenzeneparasulphonic Acid	28
Azo-colouring Matters	29, 215	Colour from Nitrosodimethylaniline	105
Azo-colours, Separation of	516	Colour from Paraazobenzenesulphonic Acid	213
Azonaphthol Colours, Constitution of	218	Colour from Pyrrol	236
Azoorthocresol Compounds, Reduction of	211	Manufacture of Laundry	104
Azoparacresol Compounds, Reduction of	211	Methylene	216, 251
Azo-S colours	412	Recorcin	250
Bacteria, Action of Electric Current on	515	Bluestone, Silver, etc., extracted from	111
Destruction of	451	Boiler or Digester	156
Bakuin (Russian Mineral Oil)	181	Boilers, Incrustation Preventive for	101, 368, 431
Balance for Use in Dye-works (illus.)	57	Injurious Action of Ferric Sulphate	469
Barium Compounds, Manufacture	108	Bone Ash, Discrepancies in Analysis of	1
Presence of, in Spanish Manganiferous Iron Ore	5	Dust, Value of Nitrogen in	185
Barley, Experiments with Nitrate of Soda	575	Dust, The Weathering of	187
Manuring	575	Meal and Kainite, Rye manured with	417
Nitrogenous Substances in	528	Meal Manufacture	575
Baryta or Strontia, Treatment of Molasses by	423	Bones, Extraction of Fat from (illus.)	375, 490
Bassia Fat	574	Etc., Gelatin, etc., extracted from	112
Batteries, Porous Pots for Galvanic	414	Peat, etc., Calciner for	410
Beck for Continuous Dyeing (illus.)	61	Utilisation	116
Beer, Artificial Cooling of	339	Boric Acid and Glycerine as an Antiseptic	121
Clarification	529	Acid, Use in Preserving Food	326, 578
Gluten Precipitate in	616	Boring Machines	374
Pasteurisation of	188	Without Cutting Tools	571
Promoting Fermentation of	189	Borneol from Camphor	328
Raised by Carbonic Acid Gas	528	Bostonite (Canadian Asbestos)	517
Thickening of Pasteurised	528	Bran, Digestibility of	186
Beers, Method of Preserving	423	Value of different Samples	185
Beet-juice, Purification	114	Braslin	242, 628
Separation of Non-saccharine Matter from	113	Brass, Crucibles for Manufacture of	32
Beet-root, Nitrate of Soda as Manure for	515	Brewing	543, 576
Preservation	327	Conversion of Starch in relation to	397
Belladonna	329	Extract of Hops for	325
Benzaldehyde and Betanaphthol, Product of	216	Treatment of Hops in	378
Orthonitro-, Product of Diethylaniline with	629	Water Softened for (illus.)	53
Paranitro-	104	Brick Kiln	639
Benzene in Coal gas	272	Bricks made from Kieselguhr	133
From Compressed Petroleum Gas	439	Made from Sewage Sludge	45
From Coal-gas	432	From Strontianite, Manufacture of Basic	33
Formation from Phenol	162	Brimstone, Import of	479
From Gases	369	Bristol Water Supply	201
Increased Production from Coal	438	Bromides, Detection of Iodides in presence of	331
Nitrification Test of (illus.)	74	Bromine, Density of	66
From Petroleum Gas	462	Employed as a Disinfectant	133
Presence of Alcohol in	80	Titrated with Beta-Naphthol	367
Rectifiers (illus.)	75	Brown, Azo-Colours from Crystoidines	28
Toluene, etc., Separation from Crude Naphtha (illus.)	73	Colouring Matters from Coal-tar	27
Benzenes, Fractional Distillation of (illus.)	565	Colours from Paradiamines	442
Estimation of Carbon Disulphide in	295	Colours resembling Indophenols	236
Recovery of, from their Sulpho-Acids	371	Manufacture of Uimin	106
Valuation of	513	Burettes (illus.)	651
Benzidine, Reaction of	533	Burcine	616
Benzoic Acid and Pyrogallol, Colour from	441	Burnettising Timber	622
Resorcinol, Colour from	440	Buckwheat, Influence of Superphosphate on	187
Orcinol, Colour from	441	Burners for Carburetted Gas	409
Benzophenone, Dioxo-	25	Butter, Shea	574
Oxyamidohomo-	25	Butylene in Coal Gas	272
Diamidohomo-	25	Bye-Laws, Modification of	394
Benzoquinone and Pyrrol, Violet Colour from	439		
Bessener Hearths, Water Cooling for (illus.)	33	Cadmium Yellow on Calico	255
Metal Manufacture	640	In Zinc Dust	523
Betanaphthol and Benzaldehyde, Product of	246	Caffeine	190, 263
Betanaphtholalphasulphonic Acid	106	Calciner for Bones, Peat, etc.	410
Betanaphtholbetasulphonic Acid	106	Calcining Ores, etc., Furnace for (illus.)	320
Betanaphtholdisulphonic Acid	244	Calcium Chloride, Utilisation of	387
Beverages, Non-alcoholic	578	Hydrosulphide	550
Bile, Determination of Ammonia in	497	Hydroxyhydrosulphide	550
Bismuth Brown on Calico	251	Hydrosulphides	481
And Copper, Quantitative Separation	115	Oxysulphides	413
Sub-nitrate, Pure	530	Tartrate, Valuation of	619
Bistres for Dyeing and Printing	29	Tartrate, Estimation of Carbonate in	619
Bisulphites, Compounds of Azo-colours with	442	And Strontium, Separation of	455
Bitumen, Analyses of	159	See Lime	
Black Ash, Assaying	18	Calico, Chlorine as a Discharge on	478
Colour from Pitch	105	Printing with Indigo (illus.)	55
Manufacture from Leather Waste	104	Printing, Mineral Colours used in	254
Pigment from Lead Fume	639	Printing, Thickenings, Resists and Discharges for	167
Blast Furnace, Behaviour of Phosphorus in	487	California, Barren Soil from	186
Furnace Slags, Utilisation of	32	Calories contained in Steam	135
Blasting Cartridges	115	Calorimeters	231
Explosives for	329, 330	Camphor, Action of Sodium on	190
Gelatine, Spontaneous decomposition of	647	Borneol from	328
Powder, Michalowski's	646	Japanese (illus.)	333
Submerged Rock	192	Matico-	263
Bleaching, Dyeing, etc., Arrangements for	170	Oil, Composition of	354
Dyeing, etc., Machine for (illus.)	477, 568	Canada, Phospho-Mining in	261
Dyeing, etc., Lancashire and Yorkshire Modes (illus.)	111	Canarin, Yellow Colour	166, 255, 476
Fibre	478, 568	Cane Juice Clarifier	645
Keir (Thompson's)	291	Canal Gas, Composition and Illuminating Power	273
Keirs for	258	Canvas, Waterproof	122
Leather	450	Carbolic Acid, Recovery of Alkali used for Extraction of	107
Ozokerit, etc.	163	Carbon Blocks for Filters, Porous	401
Paper Pulp	495	Bisulphide, Substitute for	475
Petroleum, etc.	438	Determination in Iron and Steel (illus.)	5, 33, 178, 652

	PAGE		PAGE
Carbon Dioxide, Phenolphthalein as Indicator for	156	Coal-tar Naphtha, Separation of Benzene, etc., from (illus.)	73
Disulphide, Estimation in Benzols and Naphthas	80, 295	Oils, Diphenyl in	109
Tetrachloride as Solvent for Oils and Fats	366	Phenols, High-boiling	234
Carbonates from Porter-Clark Process, Utilisation of	55	Products, Examination of	626
Carbonators for Alkali, Mechanical	607	Pyridine Bases in	159
Carbonic Acid, Apparatus for Determining (illus.)	389	Quinoline, Colours from	25
Acid, Estimation in Carbonates (illus.)	650, 632	Yellow, Orange and Brown Colouring Matters from	27
Acid, Gas, Manufacture	373	Cobalt, Extraction from Ores	524
Acid, Pure from Limestone (illus.)	568	Manufacture and Alloys	32
Acid Used for Raising Beer	528	And Nickel, Manufacture of	261
Anhydride in Coal Gas	272	Cocainin	27
Oxide in Coal Gas	272	Cochineal, Colouring Matter of	27
Oxide, Detection of, in Blood	579	Price of	257
Carbonyl Chloride, Colours obtained by action of	175	Cocoa-nut Meal as Food for Horses	122
Carboy Baskets	173	Coerulein	627
Carburetted Gas	435, 234	Coerulein, Wool dyed with	600
Carburetted Gas and Air	517	Coke, Analysis of	512
Carnalsurrogat	117	From Bituminous Shales, Nitrogen in	216
Carnallite as Substitute for Kainite as Manure	418	Composition of	563
Carnauba Wax, Composition of	201	Density of	610
Cartouche or Boiler for Heating Fats (illus.)	115	Furnaces, Regenerative	564
Cartridges for Blasting	191	From Lined Coal	13
For Liquid Explosives (illus.)	629	Manufacture	472
Casein, New Treatment of	512	Manufacture, with Recovery of By-products (illus.)	503, 561, 562
Castor Oil, Examination for Acidity	578	Ovens (illus.)	101, 434, 561, 562
Cattle Food	575	Ovens, Ammonia from	435
Food, Decorticated Cotton Cake as	186	Ovens, Comparison of By-products from	605
Foods, Analyses	192	Ovens, Earliest forms of (illus.)	601
Cellulose, Is it a Food?	209	Ovens, Gas from Tar Yielded by	467
From Jute	206, 291	Ovens, etc., Tars from	64
Oxidation of (illus.)	300	Ovens, with Utilisation of Gases	369
In Seaweed	110	Specific Gravity of	512
Cement for Casts, White	571	Weight per Bushel	611
Containing Magnesia	485, 522	Cokes, Nitrogen in Various	251
Decomposition by Water	373	Coking, Earliest Methods with Recovery of Products (illus.)	601
Detection of Adulterations in	269	Coldchicine	530
Hardening	520	Cold, Methods of Artificial Production (illus.)	357
Kilns (illus.)	30, 31	Coloured Goods, Neutral Soaps for	181
Manufacture	639	Colouring Matters from Aromatic Acids	410
Slowly Setting Portland	521	Colours from Aromatic Monamines	244
Testing	109	Colouring Matters, Basic and Acid	208
Metallic	145	Matters, Red Violet	475
Cements	110	Colours, Basic and Acid Coal-tar	117
From Silicious Earths, Hydraulic	521	New Yellow	475, 476
Properties of Various	373	Combustion of Coal Gas, Products of	513
Specific Gravity of	376	Products of	231
Cerium, Soluble Neutral Salts of	224	Condenser for Naphtha, etc.	157
Charcoal, Nitrogen in	182	Cooking Utensils, Nickel-plated	178
Superphosphates from Animal	70	Cooling, employed for recovery of Sulphate of Soda	613
Chemical Industry, History of Development of	592	Cooling, Analysis of Commercial Native	374
Technology, Remarks on Teaching and Derivatives	184	Copper, Analysis of Quantitative Separation	115
Cherries, Development of	231	Copper and Bismuth, Quantitative Separation	524
Chimney Gases, Sampling	26	Copper extracted from Solutions	613
Chloral and Dimethylaniline, Colouring Matter from	254	Extractors, Sulphate of Soda from Waste Liquors	415
Chlorates, Action in Dyeing	331	Freed from Arsenic	415
Chlorides, Detection of Iodides in Presence of	343	Matters, Treatment of	717
In Healthy and Unhealthy Plants	111	Ore, Cornish, Assay of	255
Chlor-indigo	652	Phosphate on Calico	125
Chlorine, Decomposition of Minerals by (illus.)	178	Rate of Solution in Aqueous Ammonia	423
As a Discharge on Calico	259	Solution, Reduction by Dextrose	622
Estimation of available	115	Sulphate, Timber treated with	368
Estimation in Presence of Thiocyanides	173, 319, 390, 482	"Corrosiv," an Incrustation Preventive	622
Manufacture (illus.)	411	Corrosive Sublimates, Timber treated with	575
Chlorobenzaldehyde	127	Cotton Cake, Decorticated	258
Cholera, Cause of Outbreaks	615	Chromic Yellow on	517
Chromate, Process of Tanning	610	Determination in Tissues	107
Chrome Iron Ore as Lining for Bessemer Converters	254, 258	Dyeing Loose	257
Yellow on Cotton	255	Hanks, Aniline Black on (illus.)	185
Chromium Oxide on Calico	457	Seed crushed from Undecorticated Seeds	527
Oxide, Oxidation and Estimation of	161, 212	Seed, Melitose from	181
Chrysanthine	28	Seed Oil	541
Chrysoidines, Brown Azo-Colours from	164	Seed Oil, Examination for Acidity	568
Chrysophenol	143	Cotton and Silk Goods, Dyeing Mixed	372
Citric Acid, Detection of Tartaric Acid in	527	And Silk Goods, Dyeing in Two Colours	84
Acid in Leguminous Seeds	645	Counter for use with Sprengel Pump (illus.)	142
Clarifier for Cane Juice	231	Crabbing Machine (illus.)	318
Coal, Air required for Combustion of	236	Cresotic, Determination of Phenol in	623
Ammonia and Tar from	159	For Timber, Examination of	622
Analyses of	512	Cresosoting Timber (illus.)	162
Analysis of	203	Cresol, Action of Phosphorus Trisulphide on	239
Average Composition of	256	Cresols, Azo and Diazo Compounds of	628
As a Black on Calico	134	Crocin	628
Cleaning and Sifting	563	Crocoese	321
Composition of	175	Crucible Furnaces	572
Distillation of	223	Crucibles for Steel	610
Heating Value of	222	Crushers for Ores, Quartz, etc.	566
Incineration with Steam (illus.)	438	Cumidine, Yellow Colours from	121
Increased Production of Benzene from	374	Cuprammonium Compounds	452
Mines, Ventilation by Fans	218, 234, 563	Cupric Hydrate, Action on Sugars	175
Nitrogen in	438	Cupiferous Pyrites, Treatment of Rio Tinto	181
Preliminary Treatment of	624	Currants, Development of	570
For Steam Boilers	231	Cyanides from Trimethylamine	186
Table of Products of Distillation	374	Dari Seeds, Composition of	511
Coal-cutting Machines	566	Decane in American Petroleum	234
Coal-duff, Utilisation of (illus.)	107	Decimal Weights and Measures, Objections to	234
Coal-gas, Ammonia from	432	Decyl Alcohol	234
Benzene from	271	Chloride	234
Composition and Illuminating Power	13	Hydride	234
Determination of Ammonia	438	Decylene	188
Hydrocarbons from	23	Defecating Saccharine Liquors	436
Manufacture from Slack Coal	15	Dehydrating Agent, Anhydrous Oxalic Acid	75
Sulphur in Manchester	71	Dephlegmator, Benzene (illus.)	6
Coal-tar Colours, Discovery of	626		
Estimation of Xylenes in			

	PAGE		PAGE
Dephlegmators for Valuation of Benzenes	513	Ether, Machine for Freezing	359
Dephosphorisation of Iron	111	Specific Gravity Table	351
Dephosphorising Process Slugs, Phosphates from	415	Ethylene in Coal Gas	272
Depolarising Electrolytic Baths	32	Illuminating Power of	271
Desoxyaniline Acid	263	Evaporation, Apparatus for Continuous (illus.)	469
Dextrin Achroo	400	Evaporation and Distillation, Pan for	407
Erythro	400	Explosion, Velocity of	192
Dextrose, Action of Soda Solution on	452	Explosives (illus.)	616
Formation of Mannite from	187	For Blasting	329, 330
Diamidohomobenzophenone	25	Improvements in (illus.)	190
Diamond Drill	371	Manufacture	35, 532
Diastase, Action on Starch	399	Manufacture from Molasses	35
Estimation of	528	"Extincteurs"	317
Found ready formed in some Vegetable Products	401	Fabrics coated with Xylonite	477
Diazoamidobenzene	370	Coloured, Behaviour to Water and Air	476
Diazo-colouring Matters	142	Fabrics, etc., rendered Waterproof	415
Dibromoquinone Chlorimide	237	Farms, Sewage	41
Phenolimide	237	Fat, Bassia	571
Diethylanilineazobenzeneparasulphonic Acid, Blue Colour from	28	From Bones, Extraction of (illus.)	33, 375, 490
Digester or Boiler	156	Gas from	559
Digestors, Lead Coating for	491	Of Chinese Tallow Tree	181
Digester for Pulp (illus.)	491	Fats, Detection of Hydrocarbons in	322
Dimethylaniline and Chloranil, Colouring Matter from	26	Estimation of, by means of Bromine	366
Dimethylaniline, Colours from	515	Examination of	611
Colours obtained by action of Phosgene Gas on	319	Extraction of Glycerine from	33, 31, 112
Dimethylphenylene Green	28, 258	Refining and Purifying	33
Dimethylpropylpyrogallate identical with Picamar	162	Fats, etc., Saponified by means of Zinc Oxide	112
Diorrexine (an Explosive)	192	Fats, Solubility in Acetic Acid	521
Dioxybenzaldehyde	516	Fatty Acids, Solidifying Liquid	419
Dip Pipes (Gas-making)	435	Oils, Solidification of Liquid (illus.)	260
Diphenyl in Coal-tar Oils	469	Fehling's Solution, Experiments with	423
Diphenylamine, Metoxy-	164	Ferment, Acetic Acid (illus.)	406
Paroxy-	161	Lactic Acid (illus.)	406
Diphenylamine, Synthesis of Acridine from	471	Ferments	545
Diquinoline, Pyrogenic formation of	626	Reduction of Nitrates by	185
Diquinoline	626	Fermentation	403
Diresorcinol	476, 628	Promoted	189
Diresorcinolphalein	476	Fermented Liquors, Preservation of	327
Discharges for Calico Printing	149	Ferrie Sulphate, Injurious Action on Steam Boilers	409
Disease, Germ Theory of	517	Sulphate for Detection of Iodides	331
Disinfecting Apparatus (illus.)	591	Ferrocyanides, Extraction of	173
Disinfection, References	625	Fertilisers, Artificial	112, 187
Distillation and Evaporation, Pan for	407	Manufacture	34
Fractional (illus.)	513, 565, 625, 650	Fibre for Paper-making	190
In Vacuo, Regulator for (illus.)	580	Fibres, Bleaching and Scouring	478
Distillers' Residues, Treatment for Cattle Food	578	Filter-presses for Sewage Sludge (illus.)	42
Distilling, Conversion of Starch in relation to	397	Filters	124
Doctors for Calico Printing, Composition of	110	Chemical and Mechanical	130
Drinks, Unfermented	529	Porous Blocks for	101
Drop Method of Analysis	496	For Syrups, etc.	375
Drying Arrangement for Fabrics	170	Filtration Apparatus (illus.)	651
Cylinders for Printed Calico (illus.)	58	Of Potable Water (illus.)	126
Dung Beck, for Printed Calico (illus.)	60	Of Sewage, Intermittent	41
Dunham Park, Cause of Decay of Trees in	342	Fire Engines, Chemical	317
Dye Beck for Calico (illus.)	61	Fish, Arrangements for Freezing (illus.)	359
Dyeing, Action of Hypochlorites and Chlorates in	254	Fixing Colours on Fabrics	170
Beck for Continuous (illus.)	61	Flask Apparatus for Ether Extractions (illus.)	618
Bleaching, etc. (illus.)	477	For Fractional Distillation (illus.)	627
Bleaching, etc., Arrangements for	170	Flavaniline (Yellow Colour)	28, 476, 515
Bleaching, etc., Lancashire and Yorkshire Modes (illus.)	141	Flavine, Yellow Dye containing	112
Bleaching, etc., Machine for	568	Flavolin	28
Effect of Temperature in	215	Fluorene, Phenol of	319
Fibres, Yarn, etc. Apparatus for (illus.)	29	Fluorescein, Formation of	439
Loose Cotton Black	107	Fluorols	319
Machine for (illus.)	478	Azo-Colours from the	214
Mixed Cotton and Silk	372, 568	Fluorylamines	319
And Printing, Bistres for	29	Fluxes for Preparation of Tin Plates	111
Processes, Modern	256	Food, Absorption of Lead by	493
Turkey-red	30, 106	Manufacture of Farinaceous	528
Wool with Alizarin and its Derivatives	591	Method of Preserving	424
Dyed Fabrics (illus.)	143	Preserving, Use of Boric Acid	326, 578
Dyers and Colourists, Society of	356	Formic Acid, Detection of Acetic Acid in	580
Dyes, Azo	29	Fossil-meal (Kieselguhr)	134
Dye-woods, Extraction of Colours from	370	Fractional Distillation (illus.)	625, 650
Dynamite Cannon	532	Freezing Machines (illus.)	339
Effect of Freezing on	191	Fruit, Milk, etc., Preserving	289
Efficiency of	646	Fucus Vesiculosus, Salts from	299
Kieselguhr	133	Fuel, Artificial	134
Earthenware, Enamelling	174	Use of Gaseous with Gas Retorts (illus.)	89
Naphthalene used in making Porous	109	Fuels, Mineral	159
Ebonite Press Plates for Powder Cake	191	Funnel, Condensing (illus.)	630
Echurine (a new Yellow Dye)	112	Separating (illus.)	650
Electric Light in Powder Mills	532, 617	Furfuran, Resemblance to Benzene and Thiophene	439
Lighting compared with Gas—in relation to Vitiatio		Furfural	511
of the Atmosphere	23	Furnace for burning Hydrocarbons	472, 473
"Electric" White Lead, Gardner's	348	For Crucibles, Small (illus.)	512
Electrical Insulators, Compound for	190	Furnace Furnes, etc., Extraction of Sulphurous Acid from	107
Purposes, Selenium for	321	Furnace for Gas Retorts, Regenerative (illus.)	471
Electricity, Alcoholic Liquors treated by	189	Furnace Gases, Ammonia from	415
Employment in Chemical Industries (illus.)	260	Gases, Recovery of Sulphurous Acid from (illus.)	570
Influence in Brewing	541	For Reducing Zinc	639
Electrolysis applied to Preparation of Indigo Vat	518	For small Pyrites	173
Electrolytic Baths, Depolarising	32	Utilisation of Waste Heat from	67
Extraction of Metals	322	Furnaces, Advantages of Mechanical	607
Formation of Persulphocyanogen	629	For Crucibles	321
Embossed Designs on Plush, etc.	106	For Generating Gas	232, 233
Emery, Substitute for	31	Regenerative (illus.)	91, 93
Enamelling Cast Iron	111	Regenerative	561, 565
Moulded Articles	171	Reverberatory	418
Enamels containing Lead, Poisonous Properties of	578	Fusain, Analyses of	159
Erythroxetrin	400	Fuse, Waterproofing the Bickford Safety	192
Ether, Extraction of Liquids with (illus.)	618	Galleine, Wool Dyed with	600
		Gallisin, Unfermentable Substance in Starch Sugar	453

	PAGE		PAGE
Gallotannic Acid, Estimation of	83	Haematoxylin	212, 628
Galvanising Iron	322	Halogens in Side-chains of Aromatic Compounds, Determination of	455
Gas and Air, Carburetting	231	Hampers for Carboys, etc.	173
Analysis Apparatus (illus.)	369	Heat, Digestibility of	186
Analyses of Generator	96	Heat Absorbed in Incineration of Coal with Steam	224
Analysis, Method for use in Gas-works (illus.)	12	Action in Bleaching	207
Ascension Pipes, Cause of Stoppage in	100	Lost from Retort Settings	95
Burner, Regenerative	233	Utilisation of Waste	67
Burners for Carburetted	409	Heating Apparatus for Air (illus.)	56
From Coke Ovens, Analysis of	508, 512	Values of Coal and Gases Produced	223
Combustion Products of	513	"Helianthin," Method of Preparing	410
Composition of New York	467	Helichrysin	516
Extraction of Hydrocarbons from	475	Hemlock Pine, Tannin of	525
Flames, Illuminating Power of Angular Rays	282	Herring Waste, Manuring Experiments with	417
Furnace, Small, for Laboratory purposes (illus.)	512	Hides, Unhairing, etc.	34
Furnaces used in Iron Works	99	Hops, Extract of, for Brewing	325, 376
Generators (illus.)	90, 91, 408, 409	Extracting Essential Oils from	236
Generators, Application of Steam in	470	Treatment of	578
Hydrocarbons from Petroleum	437	Treatment of, in Brewing	422
Lighting compared with Electric in relation to Vitiolation of the Atmosphere	23	Utilisation of Spent	422
Mains, Naphthalene Deposited in	158	Horses, Cocoa-nut Meal as Food for	366
Making, Cooper's Lime Process	12	Hospitals, Cooling Arrangements for	413
Manufacture	232, 233, 135, 436	<i>Huile Tournaise</i>	319
Manufacture (illus.)	556	Hydrazines, Indols from Aromatic	21
Manufacture from Oil (illus.)	462	Hydroacridine	20
Manufacture, Regenerative Furnace for	565	Hydrobromic Acid, Methods of Preparing	23
And Oil from Minerals	566	Acid Used in Oxidation of Sulphides	231
Producer (illus.)	232, 233, 473	Hydrocarbons from American Petroleum	438
Producers, Ammonia from	435	From Coal-gas	322
Producer, Tars from the Sutherland	9, 61	Detected in Fats	472, 473
Producer used at Ischl Salt Works (illus.)	172	Furnace for Burning	259
Production of Heating	233, 431, 437	Hydrochloric Acid from Ammonia Soda Process Liquors	205
Purification of	21	Acid, Effect on Various Plants	172
Purifiers, Utilisation of Lime from	563	Acid, Manufacture of Gaseous	633
Regulator (illus.)	89	Acid, Manufacture in Germany	456
Retorts, Gaseous Fuel Applied to the Heating of (illus.)	473	Hydrocyanic Acid, Notes on	111
Retorts, Mechanical Charging and Discharging (illus.)	21	Hydro-extractor, with Continuous Action (illus.)	569
Retorts, Pressure Reliever for (illus.)	171	Hydrogen, Carburetted, Impure (illus.)	272
Retorts, Regenerative Furnace for (illus.)	16	In Coal-gas	233, 496
Yield from Lined Coal	609	Manufacture	517
Works, Advantages of Machinery in	603	Peroxide, Antiseptic Properties of	496
Works, Coke Ovens at	274	Peroxide, Manufacture (illus.)	456
Works Statistics	233	Peroxide, Reaction for	553
Works, Treating Spent Lime	159, 163, 630	Sulphide, Oxidation of	371
Gases, Ammonia from (illus.)	369	Hydrolysis of Sulphonic Acids	170
Benzene from	369	Hydrometer for Brine (illus.)	407
From Coke Ovens, Utilisation	416	For Lecture Illustration	166
Evolved from Steel Castings	225	Hydroxylamine, Application for Printing	451
In Gay-Lussac and Glover Towers	271	Salts, Influence on Plants	166
Illuminating Power of Mixed	202	Silver Medal offered for Cheap	329
Injury to Vegetation done by	322	Hydroxypyridine	328
Iron Ores Reduced by	580	Hyoscine	65
Laboratory Apparatus for Drying and Washing (illus.)	221	Hypobromite Solution, Stability of	251
In Lead Chamber, Distribution of	369	Hypochlorites, Action in Dyeing	30
Production and Purification	89	Hyposulphites, Manufacture of Alkaline	359
Gauge, Calibration of McLeod's	58	Ice-making Machines	571
Low Tension (illus.)	225	Ilipie Oil	621
Gay-Lussac Tower, Gases in	636	Illuminating Power of Amyl-compounds	434
Tower, Loss of Nitrate by	112	Incrustation Preventives	101, 368, 421
Gelatin, etc., Extracted from Bones, etc.	46	Incrustations Removed from Sugar Boilers	112
Generator Gas, Analyses of	90, 91	India-rubber Compounds	443
Generators, Gas (illus.)	571	Fabrics	645
Geranium, Algerian Oil of	630	Hose	81
Germany, Alkali Industry in	418	Quantity Annually Imported into Liverpool	105
Germination of Seeds	109	Indigo, Artificial	319
Gilding Porcelain to Resemble Chasing	119	Assay, by means of Spectroscope	411
Glasgow Section, Inaugural Address	263	Blue, Constitution of	105
Glass, Arsenic in, a Source of Error in Analysis	111	Chlor-	105
Soluble, Purification of Beet Juice by means of	103	Derivatives of	105
Manufacture in Pit Furnaces	109	Paramethyl-	55
Tinted Transparent Designs on Dull	109	Printed on Calico (illus.)	28
White Lime and Alumina	225	Substitute for	515
Glover Tower, Gases in	560	Substitution Derivatives of	518
Improved	452	Test for	165
Glucose, Biotary Phenomena of	375	Tetrachlor-	516
Made from Wood	113	Treatment of	518
Manufacture	116	Valuation by Spectroscope	518
Syrup, Manufacture	646	Vat, Application of Electrolysis to Preparation of	319
Glue, etc., from Bones	490	Indigotin, Comparison of Samples	237
Gluten Precipitate in Beer	112	Indoaniles	319
Glycerine, Determination by means of Index of Refraction	449, 450	Indols, Synthesis	236
From Fats, Extraction of	33, 34	Indophenols	163
Manufacture	33, 34	Indulins	491
Preparation of, from Fats	573	Industrial Processes, Pollution of Streams by Waste from	321
Purifying	415	Insecticide, Employment of Pyridine Bases as	24
Soap, Transparent	321, 524	Prepared from Foul Gas-lime	64
Gold Extracted from Copper Mattes and Ores	514	Saponified Rosin Oil as an	343
Extraction from Ores	150	Insects, Damage done by, often attributed to Fumes	190
Grape Sugar, Manufacture	201	Insulators, Compound for Electrical	452
Graphite, Analysis of	28, 238	Invert Sugar, Action of Soda Solution on	402
Grass, Effect of Acid Gases on	250	Invertin, Reaction of	331
Green, Dimethylphenylene	263	Iodides, Detection in Presence of Chlorides and Bromides	290
Methyl-	418	Iodine, Loss in Kelp Burning	298
Guanine	113	Present Price of	641
Guano, African	329, 330	Solution for Examination of Fats and Oils	288
Discrepancies in Analysis of	330, 533	Iron, Action of Nitrates on	32
Gum Tragacanth, Treatment of	648	Alloys with Nickel and Cobalt	430
Gun Cotton, Experiments with Compressed	378	And Alumina as Causes of Reduction of Superphosphate	180
Gunpowder Manufacture	262	Aluminium Sulphocyanide free from	130
Pyrographic Method for Testing	443	Etc., Coated with Lead	111, 180
Gun Cotton, Waterproofing Compressed		Dephosphorisation	
Gutta-percha Compounds

Machine for Dressing (illus.)	640	Matches, Manufacture (illus.)	373
Preliminary Treatment of Hides for	34	Matico, Canphor	261
Rendered Impermeable	415	Measure Indicator for Brine (illus.)	179
Scraps, Utilisation of	450	Meat, Arrangements for Freezing (illus.)	35
Tensile Strength of	618	Meeting, Proceedings of Third Annual	386
		Meetings, Summary of Papers read at	610

	PAGE		PAGE
Meloinin	253	Nonane in American Petroleum	544
Meloinotrisulphonic Acid	246	Nonyl Alcohol	234
Melittose from Cotton Seed	327	Chloride	231
Mercury Required for Exhaustion with Sprengel Pump	87	Hydride	234
Metal Plates, Tin Coated	572	Nucin from Walnut Husks	646
Metallurgical Furnaces	448	Nutgall Tannin, Reactions of	644
Metallurgy, Progress in	186		
Metallic Salts, Removing Iron from	109	Oak Bark, Tannins of	181
Metals, Extraction by Electrolysis	260, 322	Bark Tannin, Reactions of	644
Extraction from Ores	486, 524	Bark, Valuation of	83
Metapæctic Acid from Cellulose	209	Obituary, Kolbe, A. W. H.	620
Metaxylene	351	R. Angus Smith	316
Determination of	77	Voelcker, A.	621
Methane, Dithionyl	160	Henry Watts	425
Methylacridine	24	Octane in American Petroleum	514
Methylene Blue	246, 251, 411	Octyl-hydride	234
Blue on Oxycellulose (illus.)	292	Oil and Gas from Minerals	566
Methylie Alcohol, Purifying	579	Gas, Manufacture (illus.)	162, 558
Methyl-Green	250	Illipe	571
Methyl-naphthalene, $\alpha$ - and Beta-	410	In Turkey-red Dyeing, Oxidation of	106
Methyl-orange as Indicator for Sulphites	199	Lubricating	112
Methylthiophene	370	Of Roses, Adulteration	579
In Crude Toluene	110	Purifying Machine	450
Mildew Prevented by Use of Cuprammonium Compounds	126	Refining	33, 450
Milk, Determination of Ammonium	496	Recovered from Waste	450
Fruit, etc., Preserving	189	Residues, Vegetable	573
Standard Method of Analysis	213	Trade, Notes on Indian	573
Milk-Sugar, Action of Soda Solution on	452	Oils, Adulteration of Volatile	574
Mill for Grinding Ores, etc.	317	Composition of Turkey-red	412
Mills for Indigo (illus.)	57	Cotton-seed and Palm-nut	181
Millet, Composition of	189	Detection of Alcohol in Volatile	579
Mine Engineering, Progress in	373	Essential, Extracting from Hops, etc.	376
Mineral Oils, Testing for Rosin Oil in	643	Estimation of, by means of Bromine	366
Minerals, Decomposition by Chlorine (illus.)	652	Examination of	611
Oil and Gas from	566	Extraction of Vegetable	33
Mixed Fabrics, Treatment of	413	Solubility in Acetic Acid	524
"Mode" Dyeing	257	Specific Gravities of various	367
Moisture in Coal Gas	272	Titration of, with Hypobromite Solution	65
Molasses, Extraction of Sugar from	188, 323	Oil, Treatment of Linseed	181
Manufacture of Explosives from	35	Oleic Acid converted into Palmitic (illus.)	201
Treatment by Baryta or Strontia	423	Olive Oil, Examination for Acidity	541
Monamines and Paradiamines, Colours from	250	Opium, Estimation of Morphinic	529, 530, 579
Moor Compost, Experiments on Potatoes	417	Orange Azo-Dyes	319
Moorland, The Manuring of	185	Colouring Matters from Coal Tar	27
Mordant for Dyed Alizarin Red, Resist with	62	Orcinol and Benzoic Acid, Colour from	441
Morphine, Estimation in Opium	529, 530, 579	Ores, etc., Mill for	317
Multiplicator (Petroleum Still) (illus.)	101	Smelting	610
"Muriate" Manufacturers' Syndicate in Stassfurt	309	Treatment of Complex	261, 572
Myrabolans, Valuation of	84	Orthoamidazo-compounds	248
Myricyl Alcohol	419	Orthocresol, Nitroso	245
Myrtle Wax, Examination for Acidity	512	Orthonitrobenzaldehyde	251
		And Aldehyde	27
Naphtha, etc., Condenser for	157	Orthonitrobenzyl Chloride	214
Solvent	81	Orthoxylene, Determination of	77
Valuation of Crude	5	Orthoxylidine (1, 2, 4)	250
Naphthas, Estimation of Carbon Disulphide in	295	Ovens, Coke (illus.)	101
Naphthalene, Amyl- and Propyl-	514	Oxalates, $\alpha$ - and Beta-Naphthyl and Phenyl	412
Deposition in Gas-mains	158	Oxalic Acid employed in Formation of Condensation Pro-	
$\alpha$ - and Beta- Methyl-	410	ducts	439
Used in making Porous Earthenware	109	Acid in Potatoes and Malt	181
Purification by Sublimation	474	Oxides, Metallic, Manufacture from Sulphides	32
Naphthalenedisulphonic Acids, Colours from	106	Oxamidohomobenzophenone	25
Acid, Yellow dyes from	213	Oxyaurin	253, 371
Naphthol, Beta- Colours from	567	Oxycellulose	206, 291
$\alpha$ - and Beta-, Derivatives of	163	Oxynaphthoquinoline	567
Manufacture	29	Oxypyrazols	568
Red Colours from	29	Oxypyridine from Quinolic Acid	451
Beta-, used to titrate Bromine	367	Oxymethylene	567
Naphtholgamadisulphonic, Beta- Acid	567	Ozokerit, Bleaching	163
Naphtholsulphonic Acid ( $\alpha$ )	751		
Acids, Colours from	243	Packing for Boilers, etc., Kieselguhr used as	133
Acids, Separation of Azo-Colours of	516	Padding Machine (illus.)	143
Naphthylamine Sulphonic Acid, Beta-	25	Machine for Calico (illus.)	58
Naphthylorthoxalates, $\alpha$ - and Beta-	412	Paint, Anti-fouling	181
Newcastle Section, Inaugural Address of Chairman	504	Palm-nut Oil	181
Soda Test	63	Oil, Difficulty of Sampling	310
Nickel, Extraction from Ores	524	Palmitic Acid made from Oleic (illus.)	201
Malleable	303	Pan. Safe, for Evaporation (illus.)	111
Manufacture and Alloys	32	For Treating Anthraquinone, etc., with Sulphuric Acid	29
Plating on Zinc	486	Pancastite	532
And Cobalt, Manufacture of	261	Papaverine	190
Plated Cooking Utensils	178	Paper Making	376
Nitrates, Action on Alkaline Sulphides	138	Making, Fibre for	190
Action on Iron and Sulphides in presence of Alkali	287	From Pulp made by Sulphite Process	495
Production of Ammonia from	139	Pulp, Boilers for	190
Reduction in Arable Land	185	Pulp, Bleaching	195
Nitre, Loss by Gay-Lussac Tower	646	Pulp Manufacture	416, 496
Loss of, in Vitriol Manufacture	134	Pulp, Treatment of Straw for	328
Nitric Acid, Detection in presence of other Acids	533	Pulp, Treatment for Making Parchment Paper, etc.	35
Acid, Estimation (illus.)	378	Test for Perviousness of	529
Acid, Paratoluidine Sulphate as Test for	649, 533	Waterproof	122, 579
Nitrication Test of Benzene (illus.)	74	Waterproof Varnishes for	529
Nitrocasein	629	Paraazobenzenesulphonic Acid, Blue Colour from	213
Nitroceresol, Salts used as Colours	517	Paraecresol, Azo compounds of	239
Nitrogen in Bone Dust, Value of	185	Paradiamines, Red Colouring Matters from	105
In Coal, Coke, and Tar	234	And Monamines, Colours from	250
In Coal-gas	272	Paraffin, Characteristic Odour due to trace of Xylene	80
Determination, Modification of Soda Lime Method	218	Determination in Tar	10
Discrepancies in Determinations of	4	Refining	236
Of Minerals, Production of Ammonia from (illus.)	216	Scale, Determination of Oil in	430
Nitrogenous Manure, Decomposition of	491	Paraguay Tea	115
Matters, Elimination from Fermented Liquor	327	Paranitrobenzaldehyde and Acetone	26
Nitroso-orthoecresol	245	Paranitrobenzylidene Chloride, Preparation of	104
Nitrous Acid, Estimation	533	Paratoluidine Sulphate as a Test for Nitric Acid	533, 649

	PAGE		PAGE
Paraxylene	354	Pitch, Black Colour from Coal Tar	105
Determination of	77	Treatment of	138
Parchment Paper, Manufacture	35	Plants, Action of Ammonium Sulphocyanide on	184
Paris Violets, Sulpho acids of	241	Action of Sodium Chloride and Zinc Sulphate on	416
Pasteurisation of Beer	188	Chlorides and Sulphates in	343
Patent Law, The New	11	Colouring Matters of	515
Paving Blocks from Slag	417	Influence of Hydroxylamine Salts on	451
Peas, Experiments with Crop of	420	Influence of Rain, Dew, etc., on	184
Peat, Bones, etc., Calciner for	110	Influence of Temperature and Climate on	418
Distillation (illus.)	236, 558	Lime and Magnesia in	322
Treatment of	421	Potassium Nitrate in	576
Pentamethylparaleucaniline	219	Plaster of Paris, Manufacture	30, 200
Pepsin, Reaction of	102	Platinum, Corrosive Action of Lithia on	504
Persulphocyanogen formed by Electrolysis	629	Plush, Embossed Design on	106
Yellow	166, 255	Polarimeter (illus.)	653
Petroleum for Preserving Food	424	Pollution of Rivers, Preventing	424
Petroleum, Absence of Nitrogen in American	216	Of Rivers, Bill for Prevention of	194
American, Hydrocarbons and Alcohols in	514	Of Streams	127
Application of Flashing Test	318	Of Water Supply	475
Examination of	161	Ponceau	109
Flashing Point of (illus.)	235, 506	Porcelain with Dull Gilding to Resemble Chasing	171
Etc., Gas from (illus.)	462, 539	Enamelling	109
Gas, Hydrocarbons from Compressed	437, 139	Made to Imitate Marble	414
Hydrocarbons and Alcohols from American	234	Porous Pots for Batteries	578
Lamp	101	Potash Bichromate, Antiseptic Properties of	399
Lamp for Light (illus.)	652	As Mordant for Alizarin	415
Purification of	438	Chlorate	419
Residues, Gas from	166	Chlorate, Manufacture	7, 18
Russian	501, 565	Determination	1
Russian and Roumanian	232	Manufacturers, German Association of	485
Still (illus.)	101	Report on Methods of Estimating	4
Substitute for Bisulphite of Carbon from	175	Valuation of Commercial	485
Tallow freed from Smell of	181	Potassio-stannous Chloride, Re-agent for Ammonium,	581
Testing for Adulteration with Solar Oil	232	Sodium and Lithium	310
Testing Flashing Point of	8	Potassium Chloride, Analyses of	260
Uniform Method of Testing	6	Electrolytic Production of (illus.)	331
Vapour, Physiological Action of	24	Iodide, Estimation	184
Petroleum, Light-giving Power of	564, 565	Manures	576
Pezizin	410	Nitrate in Plants	115
Phenanthrenequinone, Blue Colour from	439	Pernganganate, Titration of Manganese by	413
And Pyrrol, Violet Colour from	162	Sulphites, Decomposition by Heat	181
Phenol, Action of Phosphorus Trisulphide on	166	Potatoes, Amount of Oxalic Acid in	417, 418, 419
Colouring Matters from	318	Experiments on	575
Determination in Cresote	375	Influence of Krugite on Starch in	520
In Pinus Sylvestris	250, 252, 253, 371	Pottery Kilns (illus.)	191
Phenols, Action of Aldehydes on	214	Powder Cake, Ebonite Press Plates for	647
In Coal Tar	165	Mills, Electric Light in	646
Nitroso-	456	Michalowski's Blasting	647
Tied Colours from Anido Ethers of	28	Press for Prismatic (illus.)	191
Phenolphthalein as Indicator for Carbon Dioxide	165	Perforation of Prismatic (illus.)	455
Phenosafranine	323	Prismatic, for Heavy Ordnance	24
Phenylacridine	164	Pressure Reliever for Gas Retorts (illus.)	294
Phenylamidopropionic Acid in Lupinus	161	Printers' Bleach	206
Phenylendiamine Diphenylmeta-	325	Printing and Bleaching, Chemistry of	413
Diphenylpara-	325	Printing Blocks, Photographed	272
Phenylglucosazone	568	Propylene in Coal Gas	511
Phenylhydrazine, Combination of Aceto-acetic Ether	325	Propynaphthalene	186
with	325	Protoplasm, Albumen in Living Compared with that in	255
Compounds with Sugars	341	Dead	328
As a Re-agent for Aldehydes and Ketones	347	Prussian Blue on Calico	102
Phenyl-beta-imidobutyric Acid	411	Pseudotropine	171
Phenyl-ortho Oxalic Ether	160	Ptyalin, Reaction of	83
Phenylthienylketone	319	Puddling Furnace	407
Phosgene Gas, Colours obtained by Action on Dimethyl-	319	Pump, Development of Sprengel (illus.)	646
aniline	3, 19, 316	Pump and Syphon Combined for Acids	141
Phosphates, Analysis of	316	Purification of Waste Waters	242
Analysis of and Method of Sampling	536	Purpurin, Comparison with Anthragallo.	599
Bi- and Tri-calcium	323	Oxidation	159
From Calcareous Phosphorites	629	Wool Dyed with	159
Decomposition of	317	Pyridine	159
Mill for	111, 415, 489, 490	Hydrate	159
Treatment of Insoluble	262	Bases in Coal Tar	246
Valuation of	6	Bases, Colours from	34
Phosphate of Lime, Manufacture	239	Bases for Destroying the Vine Louse	106
Phosphatic Slags, Utilisation of	32	Bases, Red Colours from	28
Phospho Mining in Canada	261	Bases, Yellow Colours from	180
Phosphoric Acid, Determination in Manures	575	Carbonic Acid (?)	318
Acid, Estimation in Superphosphates	1	In Commercial Ammonia	566
Acid, Report on Methods of Estimating	323	Compounds	410
Phosphorites, Treatment of Calcareous	187	Constitution of	329, 377, 454
Phosphorus, Behaviour in Blast Furnace	5, 179, 321	Derivatives	160
Determination in Iron	162	Orthomethyl	328, 424
Phosphorus Trisulphide, Action on Phenol and Cresol	113	Piperidine from	329
Photographed Printing Blocks	280	Pyridinedisulphonic Acid	519
Photometer, Portable (illus.)	281	Pyrites in America, Sulphuric Acid from	173
Radial (illus.)	278	Furnace for Small	479
Universal (illus.)	564, 565	Import of	175
Photometric Value of Petroleum	621	Treatment of Cupriferos Rio Tinto	648
Standard Light	277	Pyrographic Method of Testing Gunpowder	470
Photometry, New Phases in (illus.)	370	Pyrometer (illus.)	319
Phthalaldehyde	370	Pyroacetic Acid, Indol Derivatives from	236
Phthalophenone	214	Pyrrol, Blue Colour from	161, 139
Phthalyl Chloride	370	Colouring Matters	640
Constitution of	189	Quartz, Ores, etc., Crushers for	83
Phylloxera, Slag as a Remedy for	162	Quercitanic Acid, Estimation of	191
Picamar	159	Quick Matches from Straw Haulms	639
Picolines, Isomeric	160	Quicksilver Mines in Idria, State of	245
Picolinic Acid	628	Quinaldine	245
Picrocrocin	375	Bases	244
Pinus Sylvestris, Phenol in	328, 567	Quinoline	106
Piperidine, Synthetical	421	Bases, Red Colours from	28
Synthetical from Pyridine	105	Bases, Yellow Colours from	216, 514
Pit Furnaces, Manufacture of Glass in		Colouring Matters from	

	PAGE		PAGE
Quinoline Compounds	566	Silica, Hydraulic	492
Constitution of	410	As a Manure	260
Derivatives	161, 377	Silicious Earths, Hydraulic Cements from	110
Derivatives, Synthesis	319	Silk and Cotton Goods, Dyeing Mixed	568
Formation of	474	And Cotton Goods, Dyeing in Two Colours	372
Quinol, Action of Aniline on	161	Determination in Tissues	517
Quinoline Acid, Oxypyridine from	357	Dyeing	170
Quinolinic Acid	454	Dyeing	262
Rackarock	647	Silo, Arrangement of, with Press	451
Rain, Dew, etc., Influence on Plants	181	Silos, Construction of	111
Rape Oil, Examination for Acidity	541	Silver, etc., extracted from Bluestone	415
Rectifiers for Benzene, etc. (illus.)	75	Extracted from Copper Mattes and Ores	524
Red Colours from $\alpha$ -Naphthol	29	Extraction from Ores	321
Colouring Matters from Paradamines	105	Ore, Extraction	416
Reduction of Manures	430	Size, Manufacture from Leather Cuttings	417
Refraction, Index of, Determination of Glycerine by means of	490	Slag, Paving Blocks from	489, 490
Refractory Earths, Influence of Titanic Acid on	174	Phosphates from	189
Material	230	As a Remedy for Phylloxera	489
Refrigeration Employed in Chemical Works	614	Utilisation of	187
Regenerative Furnaces (illus.)	91, 93	Slags, Analyses of	180
Regulator for Fractional Distillation in Vacuo (illus.)	580	Crystals of Silico-phosphate of Calcium in Basic	639
Resin, Analyses of Fossil	159	Decomposition of	415
Resins, Formation of	253	Phosphates from	32, 111
Resists for Calico-printing	62, 168	Treatment of Phosphatic	32
Resorcin Blue	250	Utilisation of Converter	203, 343
Resorcinol	628	Smoke, Damage to Vegetation by	555
And Benzoic Acid, Colour from	141	Snuff, Composition of	507
Action of Aniline on	164	Soap, Difficulty of Sampling	573
And Salicylic Acid, Colour from	95	Glycerine Transparent	112
Retort Settings, Heat lost from	475	Manufacture with use of Petroleum	112
Retorts for Gas	221	Refining	573
For Incinerating Coal with Steam (illus.)	219, 41	Sand	31
River Pollution, Abatement of	581	Treatment of Fats for	181
Rivers Pollution, Bill for Prevention of	424	Soaps for Coloured Goods	173
Preventing Pollution of	217, 516	Soda Arseniate	633
Roccellin	192	Soda-Ash Manufacture in Germany	47
Rock, Blasting Submerged	110	Valuation of	451
Rollers for Calico Printing, Composition of	371	Soda Bicarbonate, Manufacture	445
Ropes for Collieries	371	Chlorate	173
Rosaniline Salts, Best Temperature for Dyeing with (illus.)	215	Chromates	389
Rosanilines, Homologues and Isomers of	247	Comparative Costs of Processes	445
Roses, Adulteration of Otto of	579	Grinding Caustic	484, 485
Rosin Oil, Purification of	438	Manufacture	153
Oil, Saponified and used as Insecticide and Antiseptic	644	Manufacture, Employment of Lime Phosphates in	389
Rosolic Acid	371	New Ammonia Process of Manufacture	259, 569
<i>Rouge Végétale</i>	517	Crystals, Ammonia Process (illus.)	575
Rubifuscin (Orange-red Colour)	515	Nitrate, Experiments on Barley and Beetroot	452
Rufococcin	27	Solution, Action on Dextrose, etc.	108
Composition of	186	Sulphate free from Iron	613
Manured with Bone Meal and Kainite	417	Sulphate from Waste Liquors of Copper Extractors	7, 311
Saccharimeter, Half-shadow	527	Tests	17, 19, 63, 211
Saccharomyces Cerevisiae (illus.)	406	Tests, Lancashire and Newcastle	387
Saccharoidens (illus.)	406	Tests, Valuation of Liquors from Ammonia Process	630
Mycoedema (illus.)	406	Sodio-Calce Carbonate	190
Saccharine Liquors, Defecating or Clarifying	188	Sodium Action on Camphor	416
Saffron, Substances occurring in	628	Chloride, Action on Plants	107
Saffranine Series of Colouring Matters	28	Hydrosulphide	481
Pheno-	166	Manufacture	443
Safranines, Production of	517	Polysulphides	581
<i>Safransurrogat</i>	115	Reagent for	484
Salicylic Acid, Manufacture	571	Sulphate, Soda made from	495
Acid, Solubility in Volatile Oils	616	Sulphide Employed for making Wood Pulp	186
Acid, Synthesis	170	Soil from California, Barren	184
Salt Industry, Improvements at Ischi (illus.)	417	Influence of Cultivation of, on Nutritiveness of Straw	232
Manuring Experiments with	310	Solar Oil, Testing Petroleum for	343
Samples, Difficulty of obtaining Average	6	Soot, Damage done by	60
Sampling for Analysis	650	Souring Beck for Printed Calico (illus.)	641
Instrument (illus.)	17	Specific Gravity of Fats	124
International Methods of	210, 307, 339	Gravity of Solution of Ammonia	319, 516
Methods of	211	Spectroscopic Valuation of Indigo	320
Minerals, Method of	345, 356	Spent Oxide, Furnace for Roasting (illus.)	542
Report on Standard Methods	573	Sperm Oil, Examination for Acidity	83
Sand Soap	233	Sprengel Pump, Development of (illus.)	348
Scrubber for Gas	511	"Stack" Process of making White Lead	397, 543
For Tar and Ammonia (illus.)	417	Starch, Conversion into Alcohol	323
Sea Mud, Experiments with	297	Action of Hydrochloric Acid on	113
Sea-weed, Charcoal from	542	Drying in Vacuo	398
Seal Oil, Examination for Acidity	69	Granules, Structure of	575
Section, Address by Chairman of Manchester	119	In Potatoes, Influence of Krugite on	113
For Glasgow and the West of Scotland, Formation of	119	Manufacture	323
Inaugural Address to Glasgow	321	Manufacture from Maize	527
Selenium, Manufacture for Electrical Purposes	650	Potato, Estimation of Water in	453
Sewage, Ammonia from (illus.)	42	Sugar, Unfermentable Substance in	399
Average Composition of	11	Temperature of Gelatinisation	185
Chemical Precipitation	44	Stassfurt Manures	610
Intermittent Filtration	529	Statistics of Papers Read at Meetings	231
Filtering and Purifying	41	Steam-Boilers, Coal for	53
Of London, Solid Matter in	451	Water softened for (illus.)	135
Manure from	12	Steam, Calories contained in	407
Purification of	189	Generator by Chemical Agents	170
Purification and Utilisation	41	In Gas-generators, Application of	222
Sludge, Disposal of (illus.)	15	Incineration of Coal with (illus.)	61
Sludge, Evaporative Methods of Treatment	15	Steaming Cylinder for Printed Calico (illus.)	59
Sludge, Mechanical Methods of Treatment	48	Machine for Printed Calico (illus.)	260
Sludge, Value of	129	Steatite, Firebricks, etc., from	320
Of Towns, Disposal of	216	Steel, Cast	416
Shales, Nitrogen in Bituminous	236	Castings, Gases Evolved from	652
Containing Sulphur, Treatment of	574	Determination of Carbon in (illus.)	35
Shea Butter	614	Estimation of Carbon in	611
Ships Bottoms, Anti-fouling Composition for	614	Hardening	178
		And Iron, Examination of	319
		And Iron, Method of Distinguishing between	524
		Manufacture	31
		Methods of Manufacturing	572
		Smelting in Acid and Basic Crucibles

Waste, Recovering Oil from	450	(Top and Bottom (illus.)	406
Heat, Value of	67	Yellow Azo Dyes	319
Waters, Analyses of	578	Colouring Matters from Coal Tar	27
Water, Action on Coated Lead Pipes	493	Colours from Pyridine Bases	28, 566
Contamination by Lead Pipes	454	Dye from Alpha-naphtholmethyl Ether	106
Cooling for Bessemer Hearths (illus.)	33	Dyes from Naphthalendisulphonic Acid	213
Expansion of, at High Temperatures	68	Yorkshire Dyers, Modes Practised by (illus.)	141
Red-hot	68		
Filtration of Potable (illus.)	126		
Hardness, Determination (illus.)	652	Zinc Acetate, Tartar Emetic Adulterated with	329
Pollution of Supply	427	Alloys, Manufacture	32
Purifying	35, 529	Bromide, Preparation of	22
Softening by the Porter-Clark's Process (illus.)	51	Bromide, Preparation of Hydrobromic Acid from	20
Supply of Bristol	201	Chloride, Timber treated with	622
Waters, Purification of Waste	646	Dust, Cadmium in	523
Waterproof Compounds, Elastic	113	Free from Arsenic	486
Fabrics	415	Furnace for Reducing	639
Paper and Canvas	122	Manufacture	524
Waterproofing, the Bickford Safety Fuse	192	Nickel Plating on	486
Compressed Gun Cotton	378	Ores, Treatment of	610
Fabrics	413	Oxide, Manufacture	573
Leather	641	Oxide, Used for Saponification of Fats	112
Wax, Composition of Carnauba	448	Precipitated Electrolytically	260
Substitutes for	163	Presence of, in Spanish Manganiferous Iron Ore	5
Vegetable	574	Smelting (illus.)	178
Weights, Adoption of Uniform System	8	Sulphate, Action on Plants	416
Welding Iron, Influence of Composition on	486	Sulphide, Anhydrous	415
White, Lauth's	411	Used in Extraction of Glycerine	112
Lead, Substitutes for	350	White, as a Substitute for White Lead	350
Willensden Fabrics (Waterproof)	122	Zincammonium Compounds	121
Wine, Determination of Tartaric Acid in	326	Zinciferous Pyrites Residues, Separation of Iron from	11
Manganese in	528	Solutions from	
Promoting Fermentation of	189		

## LIST OF MEMBERS.

## A

Abel, Sir F. A., Royal Arsenal, Woolwich, London, S.E.  
 Abney, W. de W., 3, St. Alban's Road, Kensington, London, W.  
 Abraham, A. C., 87, Bold Street, Liverpool  
 Ackworth, J. J., Sheldmont House, Cricklewood, London, N.W.  
 Adam, A. Learmouth, 18, Robertson St., Greenock, N.B.  
 Adams, M. A., Ashford Road, Maidstone, Kent  
 Adams, J. W., 74, Oxford Street, Regent Road, Salford, Manchester  
 Addie, J., Langloan Ironworks, Coatbridge, N.B.  
 Adkins, H., Chemical Works, Smethwick  
 Affleck, J., 9, Challoner Terrace, South Shields  
 Ainscow, H., Messrs. Thos. Vickers & Sons, Phosphate Works, Widnes  
 Ainsworth, Thos., Holly Bank, Rochdale Road, Bury  
 Aitken, A. P., 8, Clyde Street, Edinburgh  
 Albright, G. S., The Elms, Park Road, Edgbaston  
 Albright, W. A., Mariemont, Birmingham  
 Alexander, J. O., Pln. Tuschen de Vrienden, West Coast, Demerara  
 Alexander, W. T., 20, Booth Street, Manchester  
 Aldred, C. H., St. Ann's Terrace, 150, Brixton Road, London, S.W.  
 Allen, A. H., 6, Ash Mount, Broom Hill, Sheffield  
 Allen, J., 164, Upper North Street, Poplar, London, E.  
 Allen, W. H., 38, Church Street, Toronto, Canada  
 Allhusen, A., Gateshead  
 Allhusen, Wilton, 102, Quay Side, Newcastle-on-Tyne  
 Alsberg, M. (Sondheim, Alsberg & Co.), P.O. Box 2, 437, New York, U.S.A.  
 Anderton, G. H., Howendyke, Howden, Yorks.  
 Angell, J., The Grammar School, Manchester  
 Angus, John, 1, Fenchurch Avenue, London, E.C.  
 Annandale, J. H., Polton, Midlothian, N.B.  
 Ansdell, G., Lytham House, St. Alban's Road, Kensington, London, W.  
 Ansdell, T. C., Kearsley Cottage, Farnworth, Bolton  
 Archbold, Geo., Messrs. T. Kingsford and Sons' Starch Factory, Oswego, New York, America  
 Archbutt, L., Argyle Terrace, Rose Hill, Derby  
 Armstrong, H. E., London Institution, Finsbury, London, E.C.  
 Armstrong, Sir William G., Newcastle-upon-Tyne  
 Arnott, G. W., Messrs. Arnott and Butten, Rainham, Essex  
 Arthur, W., Ringsend, Dublin, Ireland  
 Ashwell, J. R., Midanbury Lodge, Bentinek Road, The Forest, Nottingham  
 Ashworth, L., The Barlows, Radcliffe, near Manchester  
 Aston, Theo., 11, New Square, Lincoln's Inn, London  
 Atkins, S. R., Market Place, Salisbury  
 Atkinson, R. W., 44, Loudoun Square, Cardiff  
 Atkinson, W. H., 156, Camberwell Road, London, S.E.  
 Attfield, J., Ashlands, Watford, Hertfordshire  
 Aubrey, W. H., c/o C. Norfolk, Esq., 1, Cliff Terrace, St. John's, London, S.E.  
 Austin, E., 126, Bermondsey Street, London, S.E.

## B

Baggallay, Arthur, Cossipore, Calcutta, India  
 Bagnall, J., 59, Stockton Street, Moss Side, Manchester  
 Bailey, Wm., The Terrace, Oaken, near Wolverhampton  
 Bailey, G. H., 43, Ducie Grove, Oxford Street, Manchester  
 Baker, E., Stoneleigh, Eastern Avenue, Reading, Berks.  
 Baker, Harry, 262, Plymouth Grove, Manchester  
 Baker, W. G., Garden Wharf, Church Road, Battersea, London, S.W.  
 Bald, J. H., Braddock, Pa., U.S.A.  
 Ball, T. B., 12, Edmund Street, Rochdale  
 Ballard, E. G., Queen's Park, St. Helens  
 Ballard, J. F., Melrose, Sidcup, Kent  
 Balmer, Thomas, Laburnum Cottage, Halewood, near Liverpool  
 Bamber, H. K., 5, Westminster Chambers, Victoria Street, London, S.W.  
 Banister, H. C., 31 Dale Street, Liverpool  
 Bannister, R., The Laboratory, Somerset House, London, W.C.  
 Bannister, W., 108, Patrick Street, Cork, Ireland  
 Barelay, H., Rose Hill, Harrington, Cumberland  
 Barclay, Thos., 17, Eull Street, Birmingham  
 Barkas, F., Canterbury College, Lincoln, New Zealand  
 Barnes, J., 37, Avenue Parade, Accrington, Lancashire  
 Barnes, Jonathan, Buckton Vale, near Stalybridge, Cheshire  
 Barnes, R. L., Oak Hall, Buckhurst Hill, Essex  
 Barr, J., Dinting Vale, Glossop  
 Barr, R., 10, Kearsland Terrace, Hillhead, Glasgow  
 Barret, E. L., 53, Springfield Road, St. John's Wood, London  
 Barrow, J., Clayton, near Manchester  
 Bartholomew, G., Halston House, Windsor Road, Forest Gate, London, E.  
 Baxter, W. H., The Lawn, Brixton Hill, London, S.W.  
 Bayley, F. S., 88, King Street, Manchester  
 Bayley, Thos., 7, West End Chambers, Broad Street Corner, Birmingham  
 Baynes, J., jun., Royal Chambers, Seale Lane, Hull  
 Beanes, E., The Moatlands, Paddock Wood, Brenchley, Kent  
 Beaven, E. S., 5, Boreham Terrace, Warminster, Wilts.  
 Bechler, M., The Maubré Saccharine Co. Limited, Fulham Road, Hammersmith, London, W.  
 Beckett, G. H., Chestnut Grove, Chester Road, Hartford, Cheshire, and care of Messrs. Brunner, Mond, & Co., Northwich, Cheshire  
 Beckett, J. H., Miles Plating Chemical Works, Miles Plating, Manchester  
 Beekingham, J. H., Messrs. Scott Brothers, Royal Insurance Buildings, Newcastle-on-Tyne  
 Bedford, J., Woodhouse Cliff, Leeds  
 Bedson, P. P., Durham College of Science, Newcastle-on-Tyne  
 Beer, W., 30, Ashfield Terrace East, Newcastle-on-Tyne  
 Beilby, G., The Birches, Midealder, N.B.  
 Bell, G., Runcorn Soap and Alkali Co., Runcorn

- Bell, H. S., Cornwall Buildings, 37, Queen Victoria Street, London, E.C.
- Bell, J. C., Bankfield, The Cliff, Higher Broughton, Manchester
- Bell, J. L., Rownton Grange, Northallerton
- Bell, O., 13, Northumberland Terrace, Tynemouth
- Bell, T. L. G., Abbey Mills, Stratford, London, E.
- Bellingham, Wm., Dalston Distillery, London, E.
- Bendix, D., The British Alizarine Co. Limited, Silvertown, Victoria Docks, London, E.
- Benger, F. B., 7, Exchange Street, Manchester
- Benjamin, M., 43, East 67 Street, New York, U.S.A.
- Bentley, J. N., Stakehill Works, Castleton, Manchester
- Beringer, C., Rio Tinto Assay Office, Garston, near Liverpool
- Berkley, P. A., Grange Villa, Jarrow-on-Tyne
- Bernays, J., 96, Newgate Street, London, E.C.
- Berry, E. E., 8, Belle Vue, Cotham, Bristol
- Best, T. F., Aldersgate Chemical Works, Southall, Middlesex
- Bethell, R. V., 9, Belgrave Crescent, Eccles, Manchester
- Bevan, A., Bryn Chemical Works, Llanelly, S. Wales
- Bevan, E. J., 46, Talgarth Road, West Kensington, London, W.
- Bevan, I., Llanelly, S. Wales
- Bevan, S. H., Wellfield, Llanelly, S. Wales
- Beveridge, J., jun., Waterloo Road, Runcorn
- Beverly, R. J., 8, Brownswood Park, South Hornsey, London, N.
- Bibby, E. V., Garston Copper Works, Garston, near Liverpool
- Bickerdike, W. E., Surbiton Place, Preston New Road, Blackburn
- Biggs, B., 3, Lawrence Pountney Hill, London, E.C.
- Bihn, G. F., Pennsylvania Salt Manufacturing Co., Philadelphia, U.S.A.
- Billing, H. S., Messrs. Burnard, Lack, & Alger, Plymouth Chemical Works, Plymouth
- Bindscheller, R., Messrs. Bindscheller, Busch, & Co., Basle, Switzerland
- Bingley, J., Chemical Laboratory, Northampton
- Binks, J. B., 18, Esk Street, Silloth, Cumberland
- Binney, H. A., Sutton, St. Helens
- Bishop, A., Conway, Three Mills Lane, Bromley-by-Bow, London, E.
- Bishop, G. A., 1, Woodlands View, Portland Park, Hamilton, N.B.
- Bishop, H. W., 76, Lichfield Street, Walsall
- Bishop, J. S., 6, Holly Terrace, West Hill, Highgate, London, N.
- Black, Wm., St. Bede Chemical Co., Newcastle-upon-Tyne
- Blackwell, G. G., 26, Chapel Street, Liverpool
- Blagden, W. G., 1, Fenchurch Avenue, London, E.C.
- Blakie, A., 22, Devonshire St., All Saints', Manchester
- Blair, J., Irvine Bank Chemical Works, Kilmarnock, Ayrshire
- Blenkinsop, W., Garden Wharf, Battersea, London, S.W.
- Bles, A. J. S., 32, Chorlton Street, Manchester
- Blinkhorn, W. J., 31, Grove Park, Liverpool
- Blott, F., Crisp Street, Poplar, London, E.
- Blythe, F. C., Adswode, Accrington
- Blythe, H. F., Holland Bank Chemical Works, Church, near Accrington
- Blyton, J., 12, Cromford Court, Market Street, Manchester
- Boake, A., Stratford, London, E.
- Bolton, G. H., Widnes Alkali Co. Limited, Widnes
- Borland, John, Etruria, Kilmarnock, N.B.
- Borland, W. D., 39, Chissold Road, Stoke Newington, London
- Boston, H. G., Nunthorpe Crescent, Bishopthorpe Road, York
- Bothamley, C. H., Yorkshire College, Leeds
- Bottle, Alex., 4, Godwyne Road, Dover
- Boulton, H. E., 64, Cannon Street, London, E.C.
- Boulton, S. B., 64, Cannon Street, London, E.C.
- Boulton, T. S., Mountford House, Barnsbury Square, London, N.
- Bountiff, G. R., Eling, near Southampton
- Bourcart, R., Sunnyside Printworks, near Rawtenstall, Lancashire
- Bow, R. H., 7, South Gray Street, Edinburgh
- Bower, G., St. Neots, Huntingdonshire
- Bower, H., P. O. Box 2,315, Philadelphia, Pa., U.S.A.
- Bowley, Jos. John, Wellington Works, Battersea Bridge, London
- Bowman, F. H., West Monnt, Halifax
- Bowrey, J. J., Kingston, Jamaica, West Indies
- Boyd, W., Tharsis Works, East Woods, Cardiff
- Boyd, W., c/o Messrs. Tennant & Co., St. Rollox, Glasgow
- Bradbury, A., Mason's Buildings, Exchange Street East, Liverpool
- Bradley, N., 49 & 51, Chapman Street, Hulme, Manchester
- Brain, N. J., Canal Street Chemical Works, Great Ancoats, Manchester
- Bramham, W., 82, Bow Road, London, E.
- Bramwell, E., St. Helens
- Bramwell, Sir F., 5, Great George Street, Westminster, London, S.W.
- Bramwell, G. H., Cowley Hill, St. Helens, Lancashire
- Branson, F. W., 14, Commercial Street, Leeds
- Breen, George, Irvine Chemical Co. Limited, 204, Vincent Street, Glasgow
- Brenemann, A. A., 97, Water Street, New York, U.S.A.
- Brewis, E. T., Great Brunswick Street, Dublin
- Brier, John, jun., Oak Bank, Bollington, near Macclesfield
- Broadbent, J. J., Stafford House, Burney Street, Greenwich, London
- Brook, J., British Alkali Works, Widnes
- Brookes, E. A., 15, Willington Road, Whalley Range, Manchester
- Brooke, Oakley House, Edgerton, Huddersfield
- Brooks, J., Bury Street, Radcliffe Close, near Manchester
- Brotherton, E. A., Fern Cliffe, Ilkley, Yorkshire
- Brown, A. Crum, 8, Belgrave Crescent, Edinburgh
- Brown, D., 93, Abbey Hill, Edinburgh
- Brown, D., Donaghmore, Tyrone, Ireland
- Brown, H., Messrs. Grimble & Co., Vinegar Works, Cumberland Market, London, N.W.
- Brown, J., The Chemical Works, Saville Town, Dewsbury
- Brown, J. Campbell, 27, Abercrombie Square, Liverpool
- Brown, J. T., 534, King's Road, Chelsea, London, S.W.
- Brown, T., The Chemical Works, King's Lynn
- Brown, H. T., 47, High Street, Burton-on-Trent
- Brown, W., Copper Works, Macclesfield
- Brown, F. W., 35, Walterton Road, St. Peter's Park, London, W.
- Browning, W., Broad Oak, Accrington
- Brundrett, A., Rhymer Ironworks, Monmouthshire
- Brunner, H., Cliff House, Appleton, Widnes
- Brunner, J. T., Winnington, Northwich
- Brunner, J. P., 28, Exchange Street East, Liverpool
- Bryan, E., Gasworks, Beverley, East Yorkshire
- Bueh, Carl von, Aluminium Crown Metal Co., Solihull Lodge, Holyoed, Birmingham
- Buchanan, J. V., 10, Moray Place, Edinburgh
- Budden, E. R., Eversley Lodge, Ealing Common, London, W.
- Bullock, J. L., 3, Hanover Street, Hanover Square, London
- Bunby, H., Ebbw Vale, Monmouthshire
- Bunker, H. E., Old Burrows Road, Skewen, near Neath, South Wales
- Burghardt, C. A., The Owens College, Manchester
- Burnard, R., Plymouth Chemical Works, Plymouth
- Burrell, B. A., Bank Chambers, 70, South Mall, Cork
- Burton, F., 2, Green Street, Bethnal Green, E.
- Bush, R. A., 20, Artillery Lane, London, E.C.
- Bush, W. E., 20, Artillery Lane, London, E.C.
- Bush, W. J., 20, Artillery Lane, London, E.C.
- Bushell, E. D. T., Broom Hill, Great Barr, Birmingham
- Butt, E. N., Curzon Street, Mayfair, London, W.
- Butterfield, J. C., Westbury Cottage, Barking
- Button, H., Faraday Chemical Works, Ramham, Essex
- Byard, A. G., 12, Brunswick Terrace, Fisher Street, Barking Road, London, Essex

## C

- Calderwood, J., 1, Alverton Villas, Wandsworth Common, London, S.W.; and Price's Patent Candle Co., Battersea
- Caley, A. J., Chapel Field, Norwich
- Calvert, J. H., Sabden, Whalley
- Cameron, R., Priory Lodge, Blantyre, Lanarkshire
- Cammack, J., 10, Salisbury Street, St. Helens
- Campbell, A.
- Campbell, W. B., 34, Grey Street, Newcastle-on-Tyne
- Cannon, M., Beaufoy's Chemical Works, Lavender Hill, London, S.W.
- Carey, E., Widnes, Lancashire
- Carlile, T., 27, St. Vincent Place, Glasgow
- Caro, H., Mannheim, Germany
- Carpenter, H. S., 32, Holborn Viaduct, London, E.C.
- Carpenter, R. F., Bent Terrace, Prestwich, near Manchester
- Carpenter, W. L., 36, Craven Park, Harlesden, London, N.W.
- Carrick, H., Redheugh Engine Works, Gateshead
- Carruthers, J. R., 60, Robertson Street, Glasgow
- Carruthers, R., c/o Carruthers, Son & Co., 70-78, King Street, Tradeston, Glasgow
- Carnely, Thos., University College, Dundee
- Carteighe, M., 180, New Bond Street, London, W.
- Casson, R. Smith, The Saltwells, Brierley Hill, near Dudley
- Cawley, G., 2, Birch Villas, Northern Grove, Didsbury, Manchester
- Cawley, J., 278, Passaic Street, Newark, New Jersey, U.S.A.
- Chaloner, G., 247, Essex Road, London, N.
- Chambers, J. M., Te Mata, Havelock, Hawkes Bay, New Zealand
- Chance, A. M., Alkali Works, Oldbury, near Birmingham
- Chance, J. F., Alkali Works, Oldbury, near Birmingham
- Chandler, Dr., School of Mines, Columbia College, New York
- Chapman, S., 84, Eccleston Square, London, S.W.
- Chapman, W., Crescent Road, Ipswich
- Charlton, J., Crabtree Lane, Clayton, near Manchester
- Charlton, J., 42, Blackfriars Street, Manchester
- Chester, E. D., c/o Messrs. Farley & Co., 15, Philpott Lane, London, E.C.
- Chidley, J. R., Abbey Mills Distillery, West Ham, Essex
- Child, H., 6, Woodlands Terrace, St. John's, Peckham Rye, London, S.E.
- Chinnery, G. T., Redheugh Chemical Works, Gateshead-on-Tyne
- Christie, J., Messrs. John Orr, Ewing & Co., Alexandria Works, Dumbartonshire
- Christopher, G., 8, Rectory Grove, Clapham, London, S.W.
- Christy, Thos., Malvern House, Sydenham, S.E., and 155, Fenchurch Street, London, E.C.
- Chrystal, W. J., Shawfield Works, Rutherglen, near Glasgow
- Church, A. H., Shelsley, Kew, Surrey
- Claisen, Dr. L., 54, Dover Street, Oxford Road, Manchester
- Clark, A. M., 53, Chancery Lane, London
- Clark, E. B., 9, Wilton Crescent, Glasgow
- Clark, J., 138, Bath Street, Glasgow
- Clark, Jno., 35, Mariners' Cottages, South Shields
- Clark, W., 53, Chancery Lane, London
- Claudet, A. C., 10, Oak Hill Park, Hampstead, London, N.W.
- Claudet, F. G., The Grange, Weston, near Runcorn

### NOTICES.

Members are requested to notify change of address as promptly as possible to the General Secretary and to the Honorary Secretary of the Section to which they belong in order to ensure receipt of the Society's journal.

Members will please to take notice that the Annual Subscription of £1 1s. for 1884 is now due, and should be forwarded to the Hon. Treasurer, to whom also cheques and orders should be made payable.

The Proceedings of the First General Meeting (1881) of the Society of Chemical Industry have been reprinted in such size and style as to permit of their being bound up with the first volume of the Journal. Copies of the reprinted Proceedings will be forwarded by the Publishers on receipt by them of twelve penny stamps for each copy required.

Numerous inquiries have been made for complete sets of the Journal for 1882. Some of the numbers for that year are out of print. Members who have not the volume for 1882, and wish to obtain it, are invited to signify that wish to the Secretary as early as possible. If a sufficient number of applications for the complete set are received, the missing numbers will be reprinted.

### LIST OF MEMBERS ELECTED JANUARY 23rd, 1884.

Paul Naef, Ph.D., British Alkali Works, Widnes, chemist.  
John Mault, 3, Gladstone Terrace, Gateshead, secretary and manager.

Peter Filcock, Chester Road, Macclesfield, analytical chemist.

Edward Johnson, Lawton House, Rainhill, Lancashire, chemical manufacturer.

Charles J. Cross, Brentford, Middlesex, soapmaker.

Stephen Cliff, Wortley, near Leeds, fire-brick maker.

Henry Button, Faraday Chemical Works, Rainham, Essex, chemist.

Charles L. Stanley, Sandgate House, Wath-upon-Dearne, manufacturer of oleic acid, etc.

Harold H. Slater, Henningsvaer, Lofoten, Norway, analytical chemist.

Prof. A. A. Brennemann, B.S., 97, Water Street, New York, analytical chemist.

Prof. W. Carleton Williams, B.Sc., Firth College, Sheffield.

Ambrose A. Myall, A.M.I.C.E., 21, Cockspur Street, Charing Cross, London, S.W.

Frank Giesbers, 15, King's Road, St. Paneras, London, N.W., varnish maker.

Henry Glendinning, Winnington, Northwich, chemist.

Charles F. Young, 19, Queen Street, Moss Bank, Crumpsall, Manchester.

Fred. W. Simpson, 9, Hamilton Villas, Mill Hill, Derby, analytical chemist.

Iltyd J. Redwood, Young's Oil Company, Addiewell, N.B., analytical chemist.

Thomas Smith, Heriot Hill House, Edinburgh, pharmaceutical chemist.

Joseph J. Coleman, F.I.C., 45, West Nile Street, Glasgow, chemical engineer.

D. A. Sutherland, Chemical Laboratory, University of Glasgow.

J. Neilson Cuthbertson, 29, Bath Street, Glasgow, chemical broker.

W. Stewart Turnbull, Place of Bonhill, Renton, Dumbar-tonshire.

Edward B. Clark, 9, Wilton Crescent, Glasgow, chemist.

Alfred Wuth, 67, Bolton Street, Ramsbottom, near Manchester, chemist.

Jonathan Barnes, Buckton Vale, Stalybridge, chemist.

Lugh S. Powell, 56, St. James's Square, Notting Hill, London, W., electrician.

Andrew Freeman, 40, Liverpool Road, St. Helens, chemist.

Mark W. Wiley, 1, Bell Terrace, West Hartlepool, glass manufacturer.

Ernest A. Brookes, 15, Withington Road, Whalley Range, Manchester, chemist.

H. B. Lamond, Levenshulme, Manchester, calico printer.

John Marsden, Poplar House, Levenshulme, Manchester, calico printer.

E. T. Cunliffe, The Parsonage, Handforth, near Manchester.

William Crabb, Border Counties Chemical and Manure Works, Silloth, Cumberland, chemical manufacturer.

Fewster Player, Melinrythan Chemical Works, Neath, Glamorganshire, manager.  
 Hugh Barclay, Rose Hill, Harrington, Cumberland, analytical chemist.  
 Henry Shephard, 121, Townsend Street, Dublin, analyst.  
 Charles T. Macadam, 116, Fenchurch Street, London, E.C., manager of the Adams Manure Company Limited.  
 J. Grove Johnson, 23, Cross Street, Finsbury, London, E.C., assayer.  
 M. Algernon Adams, F.R.C.S., Maidstone, Kent, public analyst.  
 Thomas Hilditch, 400, Ashton Old Road, Openshaw, Manchester, chemist to Sir Jos. Whitworth and Company.  
 J. Farron Ballard, Melrose, Sidcup, Kent, brewers' chemist.  
 G. Watson Gray, 12, Argyle Road, Garston, near Liverpool, analyst.  
 T. Speakman Marsh, Connah's Quay Alkali Company Limited, Connah's Quay, Flintshire, North Wales, analyst.  
 James Hulme, 4, Alderley Street, Chester Road, Macclesfield, analyst.  
 Charles F. Cross, 16, Talgarth Road, West Kensington, London, W., chemist.

## London Section.

Chairman: David Howard.

### Committee:

Sir F. A. Abel.	R. Messel.
E. Rider Cook.	R. E. R. Newlands.
W. Crowder.	Thos. Royle.
Dr. E. Frankland.	John Spiller.
Prof. Charles Graham.	G. C. Trewby.
F. Maxwell Lyte.	C. Umney.
Geo. Matthey.	J. Williams.

Local Sec.: Thos. Tyrer, Battersea, S.W.

The meetings of this Section are held on the first Monday in each month.

On February 4th Papers will be read by Mr. C. C. Hutchinson "On the Disposal of Sewage Sludge," and Mr. J. H. Porter "On the Porter-Clark Process."

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE,  
 Monday, January 7th, 1881.

MR. DAVID HOWARD IN THE CHAIR.

## DISCUSSION ON THE DESIRABILITY OF UNIFORM METHODS AND BASES OF ANALYSIS, AND THE PRACTICABILITY OF ESTABLISHING AN INTERNATIONAL AGREEMENT CONCERNING THEM.

The SECRETARY notified the receipt of several apologies for absence, and of communications relating to the subjects under discussion.

The CHAIRMAN briefly sketched the history of the recent endeavours made abroad to obtain uniformity of analysis—endeavours which Dr. Lunge attributes to the suggestions made by Dr. Messel at the first meeting of the London Section of this Society. He strongly urged that no successful movement in this direction could do away with the need for individual skill. There would be an equal need for the "art," even if there were somewhat less of the "mystery." Any endeavour to dispense with high training and skill in the analyst would end in deserved failure. He put forward the importance of considering whether as chemists they could do anything to diminish the grave inconveniences caused in business by uncertainty in analysis, or whether they must leave that entirely to men of business, who, he feared, might adopt summary methods to obviate the difficulties, not always dictated by a knowledge of the scientific side of the question. There were a great number of substances, such as artificial manure, anthracene, benzol, and sugar, which were sold by analysis, which must be approximately uniform. He hoped that the attention of the meeting would be confined that evening to see how far a universal

agreement as to methods could be arrived at, and whether such agreement could be made international; and again (which was a subordinate branch of the subject), how far uniformity could be arrived at in stating results, and what could be done to promote uniformity of standards. This last was a most important point, and where again the international question was deserving of careful consideration. They might also consider whether anything could be done to discourage those barbarous systems of hydrometry which prevailed both in England and on the Continent. Another point, which was perhaps more difficult to take up, but which was a matter of as much practical importance as the chemical question, was that of sampling. This question had been carefully discussed by the chemical section of the London Chamber of Commerce, and he did not think he was over-stating the views of those who sat with him on that committee in saying that the most strenuous efforts would be used by the Chamber of Commerce to lend all the weight of its influence to secure uniformity in the like matters. Of course a practical mode of bringing it about was the promotion of uniformity in the terms of contracts. For, after all, the form of contract governed a vast number of these transactions. He thought chemists should have a voice in this important question, and should take part in the preliminary discussions which led to the settling of those forms of contract which were to govern these transactions. A large number of the members of the chemical committee of the London Chamber of Commerce were members of this Society, and therefore knew what they were talking about; but it was extremely desirable to consider at once whether chemists themselves could do anything in this matter or whether they should leave it to be dealt with entirely by commercial men, to make their own terms, as they had already done in certain special trades.

The SECRETARY then read extracts from letters from Dr. Lunge, Dr. Hurter, Mr. B. S. Proctor, and Mr. Thos. Farmer Hall.

Dr. Lunge (Zurich) wrote—

"I am exceedingly glad that the Council of the Society of Chemical Industry in Great Britain is taking up this question. It is doubtless the fittest body in that country to bring about practical results. Even if all that is desirable be not attained, good will certainly follow. The action of the chemical section of the London Chamber of Commerce is most commendable, and may materially assist the practical development of the question. I have taken a somewhat prominent part in the question of bringing about an international system of analysis and sampling of technical products, as my circular letter issued by you indicates. The November number of the Journal of the Society indicates very fully the position of affairs (page 411). The Wiesbaden meeting had gathered from my report that the time had hardly arrived for an international agreement, much as this seemed desirable, but it seemed hopeless to think of it till a general agreement has been arrived at by each country. Nobody dreams of 'crystallising' chemical analysis in a single shape, to the exclusion of all progress in that branch of science. The question, in the first instance, is one of 'technical' analysis, and secondly, of fixing uniform methods to be employed by buyers, sellers, and commercial analysts 'for the time being,' but subject to revision and replacement by improved methods from time to time. The German society thinks that this can be done within the limits of societies such as yours and its own. If an agreement be attained in England, Germany, and France, the methods employed in these countries might be compared at some international congress. This aim would be immensely facilitated, and even the national systems respectively be greatly benefited, if the chemists of these countries were in communication during the preparation of the standards for their individual countries. Such is my opinion, and I shall act upon it by placing at the disposal of your Society, or of any committee appointed purposely, all the material I am collecting for the German society's committee on analytical methods. The German society proceeded by appointing a committee on which each important industry has two members, who are to draw up a list of the products to be analysed and the methods best adapted for them. It is my task to mediate in case of difference, fill up the gaps, and draw up a report, which will be discussed at a full committee meeting. Its final report will be discussed at the next general meeting of the society, when probably an order will be given to embody the whole in a manual, which for a fixed time will be the standard for all

members of the society. The following are the industries represented on the committee: Tar and mineral oil distilling, Stassfurt products and potash salts, coal-tar products and organic colouring matters, alkali, organic acids and their salts, metals and their salts, and artificial manures. Most of the members of the committee have communicated with me, but some time must elapse before all the materials are collected. Still I can already see that very sound progress will be made in several, if not all, the branches concerned."

Dr. Lunge's letter was accompanied by a copy of the Wiesbaden circular and the questions propounded to the tar and mineral oil industries.

Dr. Hurter (Widnes) wrote—

"After the various Sections of the Society have decided that the subject ought to be dealt with, and can be dealt with, it should be brought forward by some competent person at the next annual meeting. A representative committee should be appointed, which should be placed in communication with the scientific bodies of the country, as indicated in your circular-letter of invitation. A joint committee thus formed should consider the question. No precepts nor directions should be given, and the committee should be free to take such steps as would conduce to a satisfactory solution of the problem."

Mr. B. S. Proctor (Newcastle) wrote to express his sense of the importance of the subject and his opinion that its accomplishment was but a question of time. After recommending action by representative committees, Mr. Proctor concludes—

"All that it would be desirable to attempt would probably follow in a natural course, and as speedily as convenience would allow, for it must be remembered that there will be inconvenience in the change as well as in the present want of agreement."

Dr. ARMSTRONG said that personally he had little to say, and that he came wishing rather to ascertain the general feeling of the members, so that he might be able to inform the Council of the Chemical Society, in order that they might be in the position, should occasion require, to take their part, as he was sure they would, in advocating this very important step. He could not say anything on the question of sampling, but with regard to the question of the uniform employment of analytical methods there could be no doubt whatever of the importance of carefully attending to the proviso which Dr. Lunge had laid down, that whatever method might be decided upon for the examination of any particular substance it would be necessary from time to time to revise it, in order that improvements might not be discouraged or prevented. There were many cases in which it was most important that a hard and fast line should be laid down—cases in which at present an exact analysis was impossible. In the case of tanning materials, for instance, there was no reliable process for the estimation of the tanning material, and therefore some kind of method might be adopted which was as nearly as possible an approach to the practical process. In such cases there should be a hard and fast line laid down and a prescribed process agreed upon. As time went on it was to be hoped that their acquaintance with the particular materials would increase, and that really scientific methods might be introduced. On the other hand, the chairman had said that there were certain cases in which uniformity was desirable, and he had referred to the case of benzol. Dr. Armstrong did not know whether he meant that seriously, but he was not inclined to think that it was altogether desirable that strict uniformity should be aimed at in cases of that kind, where it was possible to obtain a fairly-accurate estimate of the nature of the material dealt with. He thought if a scientific society were to advocate any particular standard at all it should be as far as possible a scientific standard. Of course if manufacturers chose to say they desired to have their material valued upon a certain basis well and good, but scientific chemists would not be placing themselves in the right position unless they proposed methods which were as far as possible scientific. There were one or two points which struck him as being of some interest in

the discussion which had already taken place on this subject at Liverpool. There was the interesting question of the difficulties which arose owing to different atomic weights being made use of. The case of manganese was quoted, and a suggestion was thrown out whether it would not be possible in many cases to devise standards which would be altogether independent of changes in atomic weights. That was a direction in which they might materially contribute to the desired end, and there were no doubt many cases in which it would be possible to take certain pure substances as standards to which the results might always be referred, and then, whatever change might take place in the atomic weights or factors of that kind, there would be no difficulty in testing. The majority of atomic weights were liable to considerable errors, and in some cases this might be of considerable commercial importance.

The SECRETARY then read extracts from letters from Mr. T. Farmer Hall, Mr. Kingzett, and Mr. Maxwell Lyte.

Mr. T. Farmer Hall wrote detailing the method of procedure by manure manufacturers in the analysis and valuation of their raw materials and manufactured products, and pointing out by tabulated illustrative analytical results, differences in the analyses of the same material, by equally eminent chemists, to the extent of  $1\frac{1}{2}$  to 2 per cent., and occasionally more, which in the case of ordinary raw phosphate represented 1s. to 1s. 4d per unit on an article costing £3 to £4. The discrepancies in the valuation of ammonia were of greater moment still. Mr. Hall continued—

"Four houses alone in London turned out more than 110,000 tons, and in the British Isles 750,000 to 1,000,000 tons per annum of dissolved phosphates and ammonia were produced in various forms, all of which were affected by uncertainty in the analytical results. . . . I do not intend to imply that in all cases the analysis was to blame for these discrepancies. The sampling in the cases of such materials as dissolved bones and bone manures is all-important, and unless correctly done no analyses would give concordant results. . . . Four firms had given him, worked out into money value, the differences which had occurred in 1882 between the analyses by chemists who in each purchase had acted respectively for buyer and seller. . . . This difference he found to be £3,076.

. . . Seeing these differences affect seriously a trade in which there is the keenest competition, both home and foreign, and quite apart from the professional aspect of the question, an alteration is imperatively necessary."

Mr. Hall sent a copy of the suggestions which the committee of the Association of Manure Manufacturers had prepared for remedying the evils he had described, and recommending the suitability of the Society of Chemical Industry for the work, and the formation of a consultative committee.

Mr. C. T. Kingzett wrote—

"Accepting Dr. Lunge's letter as a summary statement of the matter to be discussed, then in my opinion it would be inadvisable to establish an international agreement concerning the methods of chemical analysis. Indeed, it may be anticipated that any such agreement would interpose obstacles in the way of progress, for if all analysts were to employ identical processes for the analysis of commercial products, it would create a tendency to be satisfied with the present position of chemical knowledge, and improvements would be tardily adopted by the controlling authority, even if made. Moreover, few scientific men would be content to await official sanction to improved processes of their own devising, for such formality would be felt as a degradation to intellectual efforts. It would be difficult also to provide satisfactory guarantees for the efficient discharge of duties by the controlling authority. There should be complete liberty of action left to analysts to employ such processes or methods of investigation as they may think fit, but in cases where there is likely to be any difference of opinion, it would be well for them to describe the method pursued, so that their proceedings may be open to examination and criticism. It may be safely assumed that sooner or later, as progress is made in chemical knowledge, incorrect statements made by chemists, or inaccurate methods employed by them, will be exposed. Here, as in other matters, we must chiefly trust to enlightened public (chemical) opinion. While, however, strongly protesting against the introduction of mechanical officialism into the practice of chemical analysis I admit that the various scientific societies would do useful and important service by holding conferences concerning particular methods of analysis or by conducting collective investigations. Such a course would direct collective opinion, and thus

effect, so far as it is desirable, the object which all parties who are concerned must have in view. Scientific men of trained intelligence would surely adopt those processes which have been proved to be the most accurate. Beyond this safeguard there is the further one that manufacturers and buyers may be reasonably left to take care, in their own interests, that value, and value only, is obtained or paid for the commodities of commerce. A code such as that suggested in Dr. Lunge's circular-letter would be of no value if not made rigid and compulsory, and if made rigid and compulsory, then it would unduly interfere with the liberty of individual action as prompted by individual knowledge."

Mr. F. Maxwell Lyte, replying to Dr. Lunge's questions, wrote—

"(1) I do believe that an international agreement concerning exact standards of sampling ores, raw products, and chemicals could be attained. Such an agreement would have to be based on the use of one thermometer (say the centesimal one), on the substitution of the specific gravity enunciated as such for the diverse hydrometers and areometers in use by different nations, and probably the use of the metric system of measurement. (2) I do not believe that any similar agreement could be attained in the matter of analytical methods. (3) This has been answered in 1st. (4) The best organ would be the Society of Chemical Industry. The Society of Public Analysts would be very suitable, but they are restricted to this country, whereas the English Society of Chemical Industry is very large and important, and it possesses its counterpart in Germany, and probably will possess more in other nations of Europe. (5) The agreements might be made for an indefinite time, but the affair might be placed under the control of a committee, and sub-committees to be appointed for each country, who should revise the standards where and when necessary. (6) No remarks other than already made.

Mr. B. E. R. NEWLANDS said he had been looking at the figures on the blackboard (representing differences of results in the analysis of artificial manure), which he presumed were to be taken as somewhat bad cases. He saw there two determinations of nitrogen differing by '19 and '13, results which would be considered satisfactory if they had been obtained in a scientific laboratory. With regard to the soluble phosphates, in most cases there was no greater divergence than 2 per cent. The phosphoric acid is first determined in manures, and this has to be multiplied by about two to make soluble phosphate of it, and therefore any errors in the analysis are multiplied by two in the figures shown on the board. In most of these cases there was a difference between the two analysts of rather less than 1 per cent., and therefore there was an error of probably '45 in the phosphoric acid. This was rather more than should be the case, but he knew that these cases were exceptional, and he could speak with some authority in saying that as a rule the results obtained in this industry from public chemists were very satisfactory. With regard to the best method of obtaining results which would be satisfactory to buyer as well as seller, he thought if those branches of the chemical trade which had a difficulty in the matter, particularly the manure trade, were to agree amongst themselves to form associations and appoint as arbitrator a chemist paid by themselves, and laid down that all results should be obtained by any method the outside chemist chose to employ, but should finally, if necessary, be submitted to the arbitration of the chemist employed by the association—the association being composed of buyers, sellers, and brokers—such a plan would meet all the difficulties of the case and prevent many disputes. In the sugar trade they had such an association—the "Beetroot Sugar Association"—composed of buyers, sellers, and brokers, each class being represented on the board. These gentlemen had drawn up rules which governed the form of contracts, and the price per unit to be paid above and below certain fixed standards; the sampling was done by representatives of the association; the buyers and sellers employed their own chemists; and if the results differed more than 1 per cent. the mean of the association chemist's results and the nearest outside chemist was taken. If a Manure Makers' Association were to combine with the sellers of their raw materials and the brokers, they could with the greatest ease get a sufficiently

strong body together to be able to say we will not sell or buy on any other terms than those dictated by the association, and in a short time everyone in the trade would be compelled to come into it.

The CHAIRMAN said the Secretary had not taken the figures from the worst table, which was that of raw materials, some of the discrepancies in which were as follows: Guano, total phosphates, 40'32, 36'76; bone-ash, 73'13, 78'04, etc. He did not say that some of these errors were not due to sampling.

Mr. A. H. ALLEN (Sheffield) said: Some years ago I happened to be the secretary of a British Association committee appointed to report "On the Methods Employed in the Estimation of Potash and Phosphoric Acid in Commercial Products, and on the Mode of Stating the Results." The committee submitted a series of questions to all persons likely to be able to afford information, and they received in return a number of valuable replies, including some from leading authorities. Unfortunately, however, the replies of certain leaders of the profession were conspicuous by their absence, and the replies of others were not encouraging. Thus one firm of chemists of high standing and large experience in the analysis of both potash salts and commercial phosphates wrote: "We must decline to give you the information required, as we do not think ourselves called upon to publish our methods of analysis, which we have perfected after long and careful investigation for the benefit of those who have not taken this trouble." Again, a French chemist of very high standing, replied that he belonged to that class of chemists who could not afford to work "*pour la gloire*," but who must keep their methods—their only capital—secret. The organisation proposed by Dr. Lunge would probably be far more powerful and influential than the British Association committee, but I fear the same feeling would render the scheme abortive, and that we should still have leading chemists declining to make their processes public, refusing to work by the method which might be recommended, and persistently ignoring any criticism of their results. The British Association committee made numerous estimations of potassium as chloroplatinate, and investigated with great care the merits of various processes. How far their recommendations have done real good may be learnt from the following extract from a recent letter I have received from Mr. R. Tatlock:—

"I have never heard to what extent the conclusions of the British Association committee on potash salts were acted upon by analysts in this country. In Germany, as a matter of course, they were not adopted, as the analyses made in that country, so far as they reached me, at least, were made for sellers, and I still hold that the German method gives high results with low strength potash salts, not alone from the presence of large proportions of sodium salts but from the presence of sulphate of calcium."

Mr. Tatlock's remarks touch on another phase of the question, and that is the fact that a truthful report on samples is not always desired. In a notable instance in my own experience a client said he preferred a certificate from Dr. — ignoring the presence of 2 per cent. of sulphur and lead in an iron ore, to one from me, in which the proportion of these objectionable impurities were stated. He fully admitted their presence, so that I proved my case but lost my client. I am not sure that it might not be found in practice that the establishment of national or international methods of assaying chemical products would tend seriously to retard the improvement of chemical processes on account of the diminished encouragement which independent workers would receive. We all have an instance of what I mean in the British Pharmacopœia. The objection would be greatly lessened if the revision of the analytical methods occurred more frequently than the issue of a new edition of the Pharmacopœia, but the difficulty would be to per-

suade those responsible that their previous work was not all that could be desired. I would suggest that, after inviting communications from all practical analysts on the methods of assay to be adopted, the committee should issue a report, to be published in all chemical journals, detailing the proposed processes of analysis; and then further invite and encourage criticism from all quarters, so that, in the final report, they should have before them the views of all who cared to express an opinion on the subject. Many chemists may not feel themselves in a position to recommend or prescribe a definite method as worthy of acceptance by the committee, but on the other hand may afford much practical information on the best details of working. Again, it seems to me very doubtful how far chemists should feel themselves bound to analyse by the prescribed methods. As an instance in point, I may say that I recently examined a sample of so-called "crude naphtha," which really was a mixture of benzene and other hydrocarbons, condensed from coal gas by the process described by Mr. G. E. Davis in the December number of the *Journal*. Tested by the process described by Dr. Lunge in his work on coal tar, and stated by him to have been found to give trustworthy results, the sample in question would have been reported to yield 112 per cent. of 50 per cent. benzol. Now this abnormal result was not due to the defective working or to the inaccuracy of the method recommended by Dr. Lunge, but was owing to the fact that the so-called crude naphtha was altogether different in nature from the ordinary crude naphtha obtained by the first distillation of coal tar, and with which Dr. Lunge's method of assay gives results closely agreeing with those obtained on a large scale. (I was refused information as to the nature and origin of the sample.) Here, then, is an instance in which the chemist was bound either to modify the usual method of assay or to stultify himself; and it seems to me that the prescription of a particular method of assay in contract notes must frequently be liable to similar inconveniences, however suited such a plan may be for forming an opinion on samples of the ordinary character. If carried to an extreme, the employment of official methods would, I fear, be apt to degrade the intelligent analyst to the rank of an animated machine; and, in the long run, would be sure to react on the intellectual character and general *morale* of professional chemists. Again, several well-known analysts of iron ore having disagreed as to the proportion of manganese present in Spanish manganiferous iron ore, I was requested to look into the matter. The result was that I found the ore to contain a notable quantity of zinc, which probably by some analysts had been weighed with the manganese, and by others not, according to the process they happened to employ; but in no case had the presence of zinc in these ores been previously suspected. More recently, Mr. Riley found barium in very sensible quantity in the same class of ores—a discovery which necessitated a further modification of the process of assay. Now, had an official method of assay existed at the time I refer to the presence of these unusual elements, zinc and barium, would probably never have been suspected, and if found, the prejudice and interests of the iron-ore merchant would have prevented him from paying any attention to their existence. All these facts go to prove the necessity of prescribing such methods of assay as shall be applicable to all imaginable varieties of product, and if the methods are to do this, I fear they will have a tendency to become so complicated as to prohibit their employment in the ninety-nine cases out of a hundred in which a simpler method would give practically as good results. While I should personally view the publication of official methods of assay

of products out of my own line as highly useful to me, I am not sure that I should receive with the same favour processes dealing with products with which I was familiar; and although I should probably work by the official methods under ordinary conditions, for various reasons I certainly should not undertake to limit my discretion by never departing from them. The methods of expressing results were considered in the British Association committee on phosphates and potash salts. In these cases unanimity would seem more easy to arrive at than in that of the methods of analysis, but I am afraid that any recommendations will again be opposed by the inertia of some leaders of the profession. As an instance of the difficulty of getting any recommendation adopted, I may instance the recommendations of the Nomenclature Committee of the Chemical Society. These are very imperfectly adopted even by scientific chemists, and we repeatedly find men of the first rank writing and speaking of benzol, glycerine, gelatine, etc.

Mr. E. RILEY said the result of his experience over a great number of years was this—that the getting of accurate results did not so much depend on the method of analysis as the way it was conducted. He might get any results he pleased if he manipulated differently. His assistants frequently complained of the disappointments they met with. His reply was that only by experience could those little details be acquired which were sometimes exceedingly simple, but which made all the difference between failure and success. He had perhaps as much experience in the determination of phosphorus in one direction as anyone, and it was attended with a great deal of difficulty. Taking, for example, phosphorus in iron or steel, one might get anything one liked; and so with sulphur. It simply depended on the acidity of the solution. Where the interest of the works was in question they kept the solution a little acid, and got the phosphorus low. So with the sulphur. Again, the determination of carbon had become quite a mechanical thing; and, in fact, phosphorus also. His company was now making 1,480 tons of steel a week, and every "blow" was accurately tested for phosphorus. The result inevitably was that many of the processes became almost mechanical. The analyses were done by young men who might not be very good chemists, but they had acquired accuracy by practice. He had worked these processes out, and satisfied himself that they really were accurate. His experience had been, of course, chiefly in metallurgical products. In manganese, for instance, they always employed different weights, and the analysis was done by two different assistants, one against the other, by two different methods, and was checked by Mr. Pattinson's excellent method and the ordinary galvanimetric, and the mean of the two was taken. His impression was that Mr. Pattinson's was rather low, and the other method rather high, and so taking the mean of the two was fair. He certainly thought that methods which were known to be inaccurate should be excluded altogether. He had frequently been asked to analyse certain products by certain prescribed methods, but he always refused, on the ground that he felt himself a competent analyst. With regard to the determination of phosphorus, he added a weighed quantity of phosphorus to an ascertained amount of pure metal, and set his assistants at work to determine it, and the results came out by the methods employed exactly, which was sufficient evidence that the method of analysis was accurate. He always got the credit of finding a great deal more than anybody else, but he believed he did find all that was there.

Dr. MESSEL said: All that he had heard only confirmed his previous conviction that it was perfectly practicable to arrive at definite standards. The London

sugar refiners, the manufacturers of anthraquinone, potash salts, etc., had already done so, and he could see no reason for doing the same for copper, soda, gas-liquor, phosphates, etc., in which Mr. Pattinson pointed out that much confusion now existed. If Mr. Riley laid great stress on the quantity and strength of the test solutions which we employ and on the manipulation, why cannot the conditions be stated under which the work can be carried out most advantageously? What both buyer and seller do not desire is that each chemist who samples and analyses should arrive at a different result, as is so frequently the case. That the profession of a chemist would be lowered by carrying out the suggestions before them seemed as unfounded as to assume that the profession of an engineer had been lowered by the introduction of the Whitworth gauge for screws, or the adoption of a rational standard in lieu of the old Birmingham wire gauge.

Mr. Boverton Redwood wrote—

"The provision of authoritative rules for sampling and testing was one of the primary objects with which the Petroleum Association was founded in 1865, and considerable success has attended the efforts of the association in that direction. A uniform system of sampling petroleum burning oil is adopted by the Petroleum Association, by the Petroleum Test Bureau, in Bremen and Hamburg, and by the analogous organisation, in Belgium and Holland. The chromometric and flashing-point tests are now generally adopted, and the results are in most cases strictly comparable."

After some remarks on mineral lubricating oils, and the progress attained by him towards procuring uniformity in the methods of examination, and an expression of his readiness to personally act on any committee, Mr. Redwood

"Considers it very important there should be a generally-accepted method of estimating and expressing the chief characteristics by which the value of these oils is judged."

Mr. Watson Smith wrote—

"I have just a remark or two to offer. If an international method be agreed upon, and used for testing benzols, naphthas, etc., by a fractional distillation process, then it will not be necessary that a method involving scientific exactness and accuracy should be adopted. A method giving scope for rapidity of execution, as well as a certain amount—a sufficient amount—of accuracy, may be chosen. If, however, various methods are used, then any specially-adopted method must be the most accurate, in order to avoid the odium resulting from the comparison of 'high' and 'low' methods, by choosing the method which when challenged gives a result nearest to absolute accuracy. Suppose a method adopted universally which works with expedition, but gives with a benzol testing 90 per cent, by the most exact process only 90 per cent, *e.g.*, it might be well to adopt the more expeditious method universally as the standard method—other things being equal—because as a commercial standard once fixed it would answer the purpose just as well as a minutely-exact process requiring great expenditure of time. From this point of view I think I see positive advantage in the adoption of certain international standard methods. The necessity for such standard and fixed methods in the case of benzol and naphtha testing, in which certain small working losses must occur, is greater even than in other analytical processes, because if a sample of benzol be sent to two chemists, A and B, A being a pure scientist, with perhaps ample time to spend on a more minutely-accurate and time-consuming process, and B a commercial analyst, hard pressed for time and circumscribed as to fee, A may produce a result somewhat different from B, though both men have worked conscientiously—the results being rather the products of the methods adopted."

Mr. C. T. MACADAM said he was not prepared to speak on the scientific branch of this subject, for though he was connected with the long-suffering industry to which allusion had been made, the manure trade, he was not an expert, and therefore would not presume to offer to that meeting any observations with regard to the correct method for estimating phosphoric acid or ammonia. He left professional analysts to decide that question, but while they were discussing it he should be very glad if some uniform commercial process could be devised. No doubt there were often considerable discrepancies, and a practically-uniform method of analysis was the greatest necessity for business. A previous speaker said that soda manufacturers would not agree to a test which reduced their percentages, but the answer to that was that so long as the process was uniform the manufacturers

could adjust their prices to the process adopted. Undoubtedly chemists had cause to complain of the carelessly-drawn, and therefore imperfect, samples sent them, and he would offer a suggestion, that the sampling should, as now, be left to the buyer and seller—"mutual sampling"—but that they should draw one sample, sufficiently large, to be sent to one of the chemists named in the contract, who should divide it into three, sending part to the second analyst named in the contract, retaining the third for the umpire analyst in case of need. In that way the sampling would become more a matter for the professional analyst, who of course could not go to Blackwall, or Aberdeen, or elsewhere, to draw his own sample, but he could secure that that which he and the other chemist operated upon were practically identical.

Mr. E. W. VOELCKER said he was fully aware of the annoyance often caused by discrepancies and errors in analyses of manures, phosphatic materials, etc.; but, as Mr. Riley had stated, this was due not so much to the processes employed as to the operator, since in indifferent hands not even the very best process could be expected to give accurate results. He could not see how standard methods could be adopted when it was remembered how excessively varied in nature are the different materials which pass through the hands of an analytical chemist. To take, as a single instance, the case of phosphate analysis. Each variety of phosphate requires to be treated in a slightly different manner, according to its composition, and upon these seemingly small details depend the success and accuracy of the analysis. The question, he said, was one of experience, not of hand-books or the laying down of rules. Further, if fixed methods were laid down, the result would be to prevent the progress of knowledge amongst analytical chemists, and to tend to a perpetration of errors, even when these were known to exist. As an instance, he mentioned the case of bone ash, the phosphate of lime in which was formerly determined merely by precipitation with ammonia, the entire precipitate being reckoned as phosphate of lime, wherein it was clearly shown by Dr. Voelcker that it was in reality a mixture of the phosphates of lime and magnesia together with a varying proportion of carbonate of lime. Strong opposition to an alteration in the method of analysis, though shown to be necessary, was given by those whose interests were thereby affected, on the ground that they had been always accustomed to have bone ash analysed according to the older method. A like opposition was encountered at a later date, when it was shown that phosphates, such as Carolina, Canadian, etc., which contained fluorine and silica, required to be evaporated to dryness with acid in order to insure the expulsion of the fluorine and the rendering of the silica insoluble, thereby securing the freedom of the sulphate of magnesia precipitate from fluo-silicate of magnesia. It was complained that the new method caused a serious difference of 3 to 4 per cent. in the phosphates, but it is now generally recognised and adopted as correct. There are so many details of this kind that it is impossible to lay down rules to meet every case. The introduction of a hand-book of methods of analyses would again, he thought, tend to produce rule of thumb procedure in analyses, which would be highly objectionable.

Mr. C. NAPIER HAKE remarked that since the last meeting the Stassfurt potash manufacturers had formed a syndicate, one result of the combination being that a system more or less in force before had been confirmed, *viz.*, that all chloride of potassium should be sold according to Stassfurt analyses and weights solely. This decision might be quoted as a

prominent instance of the result brought about by differences in analyses, not by the use of different methods but simply by modification of details in carrying out one and the same method. Having had considerable experience in the analysis of potash salts, and practically tested the Tatlock method and the Stassfurt method, he was induced to say that the one employed at Stassfurt was somewhat the better—it was simpler, and less liable to error in the details of manipulation, and consequently would be more likely to insure the desired uniformity. He thought the question of a uniform system of analysis was one that could scarcely be settled between chemist and chemist, and trusted that the decision arrived at by the Stassfurt manufacturers would not prevent the bringing about of a proper understanding between the Stassfurt sellers and English buyers on lines which the Society might well suggest.

Mr. JOHN PATTINSON (Newcastle-on-Tyne) thought on the whole it was desirable that a committee should be formed to legislate upon certain matters connected with analysis of chemical products. The manure trade was one in which some fixed method was more desirable perhaps than any other of which he was aware, but at the same time there was the danger which had been already mentioned, that when once a method had been established by any authority there was the greatest difficulty in getting it altered at any future time, whatever improved methods might be discovered. If such a committee were appointed it should go very carefully to work, or it might do more harm than good to many existing chemical trades. The soda test had been frequently alluded to as a test in which unanimity was desirable. Almost ever since the establishment of the soda trade in this country it had been the practice to test soda by what was thought to be the correct equivalent of soda at that time, namely 32, which made pure carbonate of soda to contain 59½ per cent. of soda. That was the method Mr. Gossage arranged in 1836, and it was still followed throughout England. It made a difference of about 1 per cent. in favour of the alkali manufacturer, and it was very easy to see why that had never been altered after it was discovered that 31 was the correct equivalent, and that pure carbonate of soda only contains 58½ per cent. of soda. To make this alteration would at one time have meant a reduction of price of from 4s. to 6s. per ton on the product, and even at the present low price of soda it would make a difference of about 2s. per ton. In the case of soda tests, perhaps no great evil was done by retaining the old method of testing. It was well known that in England soda ash was always tested in that manner, and tables are published showing the relation of the English test to the other modes of testing. Supposing a committee were appointed, in all probability they would wish to suggest that the soda makers should immediately make the alteration to the newer and more correct test, and sell their soda by the 31 equivalent test, thus reducing the value by about 1 per cent. Was it likely they would agree to that? Unless there were a general agreement to do so amongst soda makers it would be impossible to carry out any suggestion of the kind. Again, copper ores were sold by what was known to be a very incorrect method, the Cornish assay, which was very irregular in its results, giving differences up to 2 per cent. It would be desirable, both for buyer and seller, especially for the seller, to adopt a method by which the exact amount of copper could be determined, and there are several perfectly well-known methods for doing this. But was it likely that copper smelters would follow a suggestion of this kind if made by the committee? He thought it exceedingly doubtful. Again, returning to the soda trade, his experience was that the difficulty had not

been to devise exact methods of determining the soda, but to find chemists who would do the testing correctly. The soda tests made in Liverpool were frequently from 1 to 3 per cent. higher than those made in London, on the Tyne, and in Glasgow. He had been in correspondence with most of the chemists in Liverpool, and they all told him they tested by precisely the same method as he did, namely, on the assumption that pure carbonate of soda contained 59½ per cent. of soda, and yet these differences existed. It seemed to him that these facts pointed to the want of a court of appeal rather than to a necessity for establishing standard methods of analysis.

Mr. ZIMMERMAN thought the men in every particular trade knew what an analysis in that trade was worth. His experience of twenty years taught him what price to put on a product sold by analysis when the buyer insisted on some certain analysis. Such was the case for many years in potash salts, until some short time ago Stassfurt potash manufacturers came to the conclusion that they would sell on one analysis. He was a merchant, not a chemist, and therefore could only speak from the commercial point of view. They all had their own remedies as buyers and sellers, and practically speaking they were not so much inconvenienced as outsiders would be, and perhaps it might be useful that outsiders should be a little inconvenienced. When he first came into the chemical trade and was a novice he made some foolish contracts by permitting certain English analyses, which gave when the goods were delivered here very different results from those by which he had purchased abroad; but he had gained experience, and he did not believe anyone in the room who had any commercial practical experience of chemicals would be inconvenienced or deceived; and he thought, therefore, it would not be to the advantage of the chemical trade to lay down any hard and fast lines for analysts.

Mr. DOMEIER said he was also a dealer in chemicals. He thought the middlemen were more interested in having correct results than anyone, because profits were small, and they had to rely on one analysis from the seller and another from the buyer. He found after a long time there was no practical difficulty at all in doing business as long as the mode of analysis were properly understood. The great mistake was that chemical analysis used to be considered a matter in which everyone had a method of his own, and which no one else ought to know. So soon as the method was understood difficulties ceased. The evil worked its own cure in commercial affairs, but he did not believe that English, French, American, or German chemists would differ materially in result if the method to be employed were fairly stated; but unless the method was thoroughly described results were liable to vary. Supposing an improved method was found out in six months' time, and was attempted to be introduced without due publication, difficulties would arise. In matters of trade it was necessary simply that the buyer and seller should agree; other matters could then be regulated by the price, and if the customer knew he must pay on an incorrect basis he must make due allowance for it.

Sir F. A. ABEL had listened with a great deal of interest to the discussion. He felt that the difficulties of the subject were very great, and there was much to be said on both sides. All would agree there would be great advantages attending an approach to uniformity in methods of work even if it were only in this country; but at the same time, what had been urged with regard to the attendant difficulties was quite correct, and any attempt to reduce chemical analysis to the purely mechanical was most strongly to be deprecated. He had had some little experience in

preparing directions for one or two almost purely mechanical methods of testing, with the special object of making them applicable with uniformity by operators who had no previous training, but only ordinary dexterity, common sense, and honesty; and the longer the experience he had of their general working the more he had become impressed with the difficulty in mastering the obstacles to their uniform application. Take, for example, the simple method of testing the flashing point of petroleum as an illustration of this. It was hoped that when one had arrived at an almost automatic test, and had laid down simple rules which could be followed with great uniformity one had done everything necessary; but when the test came to be applied by different people, and was used in different countries, it was found that it might yield in the hands of different operators results varying to such an extent that, superior as the test might have been to those previously used, it still left much to be desired. The same remarks applied to other tests of a mechanical nature which he had endeavoured to design for the examination of explosive compounds with reference to their proper purification. It was easy to give precise instructions for making a delicate test paper, to lay down the form and dimensions of the particular apparatus to be used, to prescribe the temperature and other details of the operation, but with all this it was almost impossible to get two persons to do the same thing in exactly the same way, and so he feared it would always be. All they could hope to do in arriving at something like uniformity was to arrive at some kind of general understanding as to methods of analysis which were considered the best, and then to apply themselves to carry these out honestly and to the best of their ability, disregarding as far as they could—it might be impossible to do so altogether—the bias both of buyers and sellers which would always exist. He did think that there ought to be no great difficulty in arriving at the greater approach to uniformity than existed at present in the statements of results. As to international uniformity, there were many difficulties to be got over before that could be arrived at. In the first place, we must all agree to discard our scruples, give up our drachms, and soberly drop grains for grammes. On this question he should like to hear the opinion of Sir Frederick Bramwell, who, though not a chemist, but an eminent engineer, was highly qualified to speak on this subject. Probably he would say that the difficulties in the way of the general adoption of the metric system was a formidable and a fundamental one, and he might probably be very much opposed to our relinquishing our system of weight and measurement, but they could all yield a little bit, and he believed even Sir Frederick Bramwell, though he entertained much respect and affection for our national weights and measures, would come to acknowledge the necessity of yielding to the tendency for uniformity. Theoretically he was as sanguine as Dr. Messel, but practically he realised the difficulties as fully as did Mr. Riley. It was one thing to lay down a method and another to carry it out, and the latter gentleman was quite right in saying that a man might make what he liked of a method. If we could only advance so far as to arrive at the understanding that such and such was the proper mode of working a particular method that would be a great step in advance towards uniformity.

Sir F. BRAMWELL said it was rather hard on him to be challenged on the occasion of his first visit to that Section to give a vindication of British weights and measures. He did not pretend to do it so far as chemicals were concerned, because he did not understand them, but he had a very strong opinion

as to the cumbrous nature of the simplicity of decimals. He believed if you wanted to make persons utterly incapable of mental arithmetic, so that they had always to cover sheets of paper so as to arrive at a certain result, and then find they were all wrong, because they had misplaced a decimal point, they should devote their minds from a very early age to decimal arithmetic. He had made it his business when on the Continent to notice the ability of persons there, in different stations of life, to do readily common arithmetical calculations, and he said advisedly that, compared with people in a corresponding state of life in England, brought up under the wretched system of tons, cwt., qrs., and lbs., and pounds, shillings, and pence, the ability of the Continental was not one-tenth part that of the Englishman. If you went to an English railway station, and asked for three tickets from A to B, you did not find the clerk take a piece of pencil or chalk to make the calculations. If there were three tickets at 3s. 4d. each, he had no difficulty in telling you at once they came to 10s.; but was it not the fact that you could not go to a Continental railway station and make a demand of that kind without the clerk behind the grating keeping everybody else waiting while he was making a calculation? If you went into a Parisian banking-house, and found a man at the counter, and tendered him a bill—again through a grating—you found a tedious calculation going on. At Milan he went into a bank to get a circular note cashed, and after a long calculation the clerk gave him 20 francs more than he was entitled to. He pointed out that what he was doing was wrong, but he insisted it could not be so, and he had to go over the whole matter carefully to prove it. Again, when he went through the engineering works at the Paris and Lyons Station, the officials there were very civil, and showed him the model of a locomotive with a very variable blast pipe. He asked them between what points they could vary it. A gentleman took a sheet of paper and figured away for a quarter of an hour, whilst he, seeing the drawing was to a scale of one-tenth, measured it at once; but he found when the gentleman had made his calculation the variation was something which would embrace the whole diameter of the chimney, and it turned out there was some error in the calculation—there always was an error in it. He was in Egypt for two years in connection with the sugar factory, and it was his fate to spend a great deal of time with the French officers in determining the sizes of the different parts. He used to give them mentally the result, and they said, "How do you do it?" He told them he turned the cumbrous decimal system into vulgar fractions, dealt with them as vulgar fractions, and turned the product back into decimals, and that he could do that in his head while they were figuring all over the paper. Was there a man present who could multiply  $3\frac{25}{100}$  by  $3\frac{25}{100}$  mentally? Suppose you were asked to square  $3\frac{1}{4}$ . 3 times  $\frac{1}{4}$  is  $0\frac{3}{4}$ , and  $\frac{1}{4}$  of  $3\frac{1}{4}$  is  $\frac{1}{4}$ , which makes  $10\frac{3}{4}$ . If you want to do it in decimals, by multiplying  $3\frac{25}{100}$  by  $3\frac{25}{100}$  you get  $10\frac{5625}{10000}$ ; but he could not do that mentally—he did it by multiplying  $3\frac{1}{4}$  by  $3\frac{1}{4}$ , and turning the product back again into decimals. Again, he should like to show how dissatisfied the French were with their own decimal system commercially. They did not write '001—they wrote  $1^{\text{mm}}$ . They did not take the metre and give the fraction of it, which was too cumbrous. Again, they did not use the kilogramme. If they looked in any of the shops they would see the goods marked up so much for half a kilogramme. No one said 500 grammes, or thought of saying 500 grammes, when they could say one half. Decimals were of the greatest use in their place, but he objected to being

compelled to use them whether he liked them or not. He would ask them to consider, and watch the next time they were travelling, whether there was not an absolute want of mental arithmetic on the Continent in consequence of this decimal system; whereas in England they went into a butcher's shop and asked how much a piece of meat weighing 8lb. 4oz. at 6 $\frac{1}{2}$ d. a pound was, and they would get the answer in a moment. If you wanted scientific accuracy in a great many places of figures you might use decimals, although then it was inaccurate compared to vulgar fractions; but if you wanted rapidity and clearness, take the ordinary vulgar fractions. How many things there were on the present system which were very easy. In his own business, for instance, if he wanted to know the weight of a boiler plate, if it was  $\frac{1}{2}$ in. thick it was 5lb. to the foot,  $\frac{3}{4}$ in. 10lb. to the foot, and so on—that was quite near enough. If he wanted to know the weight of round iron,  $\frac{1}{2}$ in. was 1lb. a foot, and any number of eighths could easily be obtained. You only had to square the diameter divided by .25, or multiply by 4, and you got the answer in pounds. If he wanted to know what weight of water fell on an acre he knew if  $\frac{1}{2}$ in. fell on an acre there were 101 tons. There were hundreds of similar cases which men who were at it all their lives knew which enabled him, old as he was, and having lost the faculty of mental arithmetic, to undertake to compete with any decimal gentlemen on any ordinary arithmetical problem—not on account of any ability of his own, but on account of using a plain, simple, intelligible mode of dealing with figures instead of the cumbrous system of decimals.

After some conversation as to the best mode of expressing the views of the meeting, it was unanimously resolved, on the motion of Mr. JOHN PATTINSON, seconded by Mr. A. H. ALLEN—"That this meeting recommends the General Council to appoint a committee composed of chemical manufacturers, consumers, and analysts, from among the members of the Society of Chemical Industry, whose duty shall be to determine in what cases, if any, it is desirable to endeavour to obtain national or international agreement, and to report to a future meeting of the Society."

## Liverpool Section.

Chairman: E. K. Muspratt.

Vice-Chairman: Prof. J. Campbell Brown, D.Sc.

Committee:

J. F. Allen. W. Douglas Herman.  
Ernest V. Bibby. E. Milner.  
Hudson A. Blinney. E. W. Parnell.  
Eustace Carey. C. Symes.  
John Hargreaves. H. Tate, jun.  
S. M. Harrison. G. T. J. Wells.

Hon. Sec.: E. G. Ballard, Queen's Park, St. Helens.

Notices of papers and communications for the meetings to be made to Edward George Ballard, Queen's Park, St. Helens.

The next Meeting of this Section will be held on Wednesday, February 6th, 1881, at seven o'clock, when the following will be the order of proceedings: (1) Discussion on Mr. Watson Smith's Paper, read December 5th, 1883; (2) Paper by Dr. Hurter, "On an Attempt to Utilise Waste Heat by means of Perkins Tubes." (3) Note on the Lancashire Soda Test, by Mr. A. Norman Tate.

UNIVERSITY COLLEGE, ASHTON STREET, LIVERPOOL,  
January 7th, 1884.

MR. E. K. MUSPRATT IN THE CHAIR.

## RESULTS OF THE EXAMINATION OF THE TAR FROM SUTHERLAND'S GAS PRODUCERS.

BY WATSON SMITH.

THE quantity of tar taken was 2.5 litres, weighing as follows: First litre, 1,085grms.; second litre,

1,090grms.; half litre, 540grms.; total, 2,715grms. Specific gravity equal  $\frac{2715}{2500}$  or 1.085. This tar, then, unlike the blast-furnace tar and the Jameson coke oven tar oils, is heavier than water, though only slightly. Mr. Douglas Herman tells me the specific gravity he has generally found with Sutherland producer tars is 1.6 T., or 1.08 specific gravity. In appearance and consistency this tar is more like an ordinary or gas-retort coal tar than either of those above referred to, but it smells differently. It would appear that its being so destitute of naphthas or spirit would at least in some measure account for its high specific gravity. Were a fair proportion of these present there can be little doubt the specific gravity would be at least somewhat lower than 1.08. I think the analytical numbers will show this, but they also show that the amount of solid carbonaceous matter and matter furnishing coke and residue are very abundant in this tar. (Compare blast-furnace tar.) The tar was in a great measure separated from admixed water by shaking round in a jar, when much of the water separates mechanically, and can be decanted off. A fresh agitation then causes further mechanical separation of water and tar. In the manner indicated a large quantity of water was got rid of before the specific gravity was determined, an important matter, considering that sometimes such tars retain as much as 30 to 40 per cent. of water, and this water, containing ammoniacal salts, has a specific gravity slightly above 1. Mr. Henry Simon, C.E., of Manchester, suggested to me the advisability of using a centrifugal apparatus for separating tar and water, much in the same way as milk and cream are separated by a process already patented. However, for working on the large scale, I consider no plan is so cheap and simple as the one recommended by Lunge in his work on "The Distillation of Coal-tar," pages 97 and 101 (Fig. 4). Of course, in the case of a tar lighter than water, the running-off cock must be placed at the bottom of the still, and, in fact, the one used for running off the pitch might serve for this purpose. In any case centrifugating could not alone be a complete process of separation; it is open, besides, to other objections, and it would hence be best and cheapest to employ one simple process.

### 2500C.C. OF TAR TAKEN, OF SPECIFIC GRAVITY 1.085.

Temperature.	Volume of Dis- tillates.	Weights of Dis- tillates.	Specific Gravity.	Per cent. by vol. of Distillates.
	e.c.	grms.		
(1) Below 230° C.....	136	130	0.956	5.11
(2) 230° to 300° C .....	250	219	0.996	10.00
(3) 300° C. till oils solidified	362	358	0.990	11.18
(4) Oils solidifying on cool- ing, or soft paraffin scale.	231	233	265	0.996
Thick oil last coming over and at once solidifying .	—	32		
Coke .....	—	830†	—	—
Loss and Water .....	—	883‡	—	—
		2715		

\* Exclusive of water. † 30 per cent. by weight on the tar.  
‡ 32 per cent.

The results of this distillation may thus be summarised:—

Total oils obtained per cent. by weight of tar taken	=36.9
Coke obtained per cent. by weight of tar taken	=30.5
Water and loss per cent. by weight of tar taken	=32.6
	100.0

The higher boiling oils show fluorescence, but not so much as similar oils from the blast-furnace tars. Fractions 1, 2, and 3 of the preceding table of results were now mixed, and the mixture was redistilled and fractionated as follows. (Total quantity taken=748c.c. or 737grms. Specific gravity=0.985.)

	Cub. cents.	Per cent. by vol. on tar.
Below 160° C. ....	Water, 13.1 (Oil, 1)	17
160 to 210° .....	22-A	0.90
210 to 220° .....	51-B	2.04
220° to 300° .....	387-C	15.50
300 until oils, on cooling, began to solidify	171-D	
Soft paraffin scale	69	
Coke remaining in retort	8grms.	
Loss on distillation	20grms.	

The results of the distillation may be summarised as follows:—

	Per cent. by weight of oils distilled.	Per cent. on tar by weight.
Total oils obtained	= 94.60	25.6
Water	= 1.72	
Coke	= 1.08	
Loss	= 2.60	
	100.00	

The three fractions marked A, B, and C, were at first of a light yellow tint, but they darkened on standing. The fraction distilling from 300 to the point at which on cooling solidification commenced, on cooling by a cold mixture solidified almost entirely. This portion was placed on a filter and allowed to drain, in order to separate the oil from the solid portions. The fraction marked A with the 4c.c. of oils distilling below 160°, were agitated with an equal bulk of caustic soda solution of specific gravity 1.085. The soda solution thus obtained was then a little more than neutralised with sulphuric acid, when 3c.c. of a dark-coloured oil separates, which on redistilling in a small bulk yielded 2c.c., between 170° and 190°, of a straw-coloured oil, which refused to crystallise on refrigerating and adding a crystal of phenol. The oil, however, contained phenol, as amply proved by the reactions, but contaminated considerably with cresol and other bodies. The fraction marked B, distilling between 210° and 220°, was cooled in a freezing mixture, but no naphthalene separated out. The fractions marked B, C, and D were now treated with sulphuric acid and caustic soda with the following results, those with B and C being very singular.\* Fraction B was treated with 3 and 5 per cent. of concentrated sulphuric acid and agitated, yet no acid tar was formed. After separation of the acid the oil was treated with ley of 18 Tw. without alteration of volume either of the oil or soda. Fraction C gave similar results. Fraction D, or rather the oils drained from the crystallised portion thereof, treated with 3 per cent. of sulphuric acid, gave a large proportion of thick dark acid tar, separating easily. The remaining oil (104c.c.) was then separated from the acid tar and treated with caustic soda solution, when the volume of the oils was still further reduced, leaving only 66c.c. finally. The volume extracted by

\* Since these results (as regards B and C) obtained by Mr. Glendinning appear to me at present explicable only on the ground of imperfect mixture, and as I let the opportunity pass of personally repeating the experiment, I shall take an early opportunity of repeating this portion of the process with a fresh sample.

soda was then 104-66=38c.c. 100c.c. of fraction (4) from the first distillation (after the solid portion had been separated) were taken and treated with acid and soda, when 86c.c. of oil remained. The oil from this fraction (4) was very thick, and ought to be serviceable as a lubricant. The results of the treatment may be thus tabulated:—

Fractions.	Volume before treatment with Acid and Alkali.	Volume after treatment with Acid and Alkali.	Loss per cent.
B (210-220) .....	51	51	—
C (220-300) .....	387	387	—
D (300-solidification) .....	174	66	62
IV (1st dist. Oils drained from crystallised matter) .....	100	86	14

The volume lost as acid tar from D=70c.c. Volume lost by treatment with soda=38c.c. The fractions above mentioned, after this acid and alkaline treatment, were collected and again distilled and fractionated: B, 51c.c.; C, 387c.c.; D, 66c.c.; IV., 86c.c.; total volume of oils distilled, 590c.c.

Temperature Centigrade.	Volume c. c.	Grms.	Specific Gravity.	Per cent. by vol. on tar.
Below 160—				
Water, 22c.c. Oil, 75c.c.	29.5	28.84	—	0.5
160-210° .....	5.5	5.67	—	
210-230° .....	67.5	66.68	0.988	2.7
230-250° .....	127.0	126.06	0.992	5.1
250-300° .....	165.5	165.78	1.004	6.6
300-350° .....	19.0	18.77	0.988	0.8
350—solidification of oils on cooling	69.0	71.6	1.038	2.8
Soft paraffin etc.	36.0	37.25	1.035	—
Last runnings	3.5	3.6	1.03	—
Coke		28.0	—	—
	523.4	552.25		

523.4c.c. - 22c.c. water = 501c.c. oils.

Total oil obtained of that last fractionated, as above, = 84.9 per cent. On standing, a considerable quantity of paraffin scale crystallised out from the fraction distilling above 350° to the point at which solidification begins. No anthracene could be detected in the solidified distillates last received over.

PARAFFIN DETERMINATION.—10grms. of the mixture of latter thick oils were treated with 108c.c. of concentrated sulphuric acid, and the whole was heated on the water-bath. It was then cooled and poured into 500c.c. of water, when on standing the paraffin separated out as a layer on the surface of the water. It was removed carefully, dried between blotting paper, and weighed. 10grms. of thick oil gave 5.56grms. of paraffin=55.6 per cent. on the thick oil, 6.7 per cent. on the tar.

In conclusion, I beg to express my best thanks to Mr. H. Glendinning, who performed the experiments described in this paper in the laboratory of The Owens College, under my direction.

The discussion on Mr. Smith's paper was adjourned, and Dr. ROBERT BOUCART read a paper "On the Process of Messrs. Schlieper and Baum, of Elberfeld, for Printing Indigo, including the Continuous Process for Dyeing Turkey Reds."

DISCUSSION ON MR. W. P. THOMPSON'S  
PAPER ON THE NEW PATENT LAW.

Dr. HURTER spoke of the provisions of the measure in the case of two applications for patents of a similar nature, and said he did not suppose the Attorney-General or the Solicitor-General would dismiss the second application if there were the slightest difference between it and the first. Moreover, the second applicant would be given to understand how far it was the same thing, and he would surely have a right to say that there was a difference in his opinion between the two. Was there no provision for this?

Mr. THOMPSON said there was this point to be considered: Supposing the difference was very slight, the first applicant, who in nine cases out of ten could get to know what the second intended, could frame his claims so as to cover both ideas. He (Mr. Thompson) had known several cases of this kind in oppositions under the old law.

Mr. HURTER doubted if the application of one person would be seen by another.

Mr. THOMPSON said it would not, but, practically, what the invention consisted of got out in nine cases out of ten.

Dr. HURTER said, of course, every patent could be annulled after the Government had sealed it by a long and costly lawsuit; but he thought it was a very good provision of the law that a patent which was manifestly known to manufacturers to be old could be killed by a simple process. Mr. Thompson was not correct in his statement that Switzerland belonged to the countries which had a union for the protection of patents. He happened to be a Swiss himself, and he knew that the Swiss people, and particularly the chemical industries, had rejected the idea of patent laws, for, Switzerland being a very small country, could not prosper if it were hampered by patents.

The CHAIRMAN said he must first thank Mr. Thompson for his able digest of the patent law. He thought clause 9—that a complete specification should not be substantially altered from the provisional one—was a most valuable clause. He did not see that any man had a right to a patent unless he knew what he wanted to patent; and for his own part, therefore, he could not see why the clause was objected to by Mr. Thompson. If a man knew what his intention was he could state it in his provisional specification. Nor could he see any harm in the provision that the complete specification should be in accordance with the provisional one. As to clause 45, which made the Act retrospective, he thought that a great mistake.

Dr. HURTER pointed out that the Act was not made retrospective in every respect—for instance, as regards compulsory licenses and the rights of the Crown.

The CHAIRMAN said he had not had time to refer to the Act himself, and after Dr. Hurter's explanation he did not see what objection Mr. Thompson could take to clause 45.

Dr. HURTER commented upon the superiority of the new Act in regard to the point which was formerly sought to be secured by the Statute of Monopolies. What would now have to be proved in order to compel an inventor to grant a licence for the use of his patent was simply that the process was not working in the country, while under the old statute it was necessary to prove damage to trade, a very difficult and intangible matter.

Mr. THOMPSON, replying to the remarks made, said Switzerland had joined the Union in regard to

patents, designs, and trade marks, and had passed a trade-mark law, but the attempt to introduce a patent law had been defeated by the vote of the inhabitants, and could not be brought in aquisition, in accordance with the constitution of the republic, till 1892. A patent office under the Union was actually being built, he had understood, in either the city of Berne or Geneva for the use of the Union. He referred next to the fee of £100 payable at the end of the seventh year, and complained that the Board of Trade had refused to accept the sum in instalments in the case of old patents on which the £50 had already been passed before the passing of the law, but insisted upon a lump sum. In one case he had appealed against this ruling to the Board of Trade, but in vain. With regard to the retrospective nature of the Act, what he wished to dwell upon was that patents which were null and void, and were being worked by others irrespective of the patentee, could be made valid, and those who worked them could be stopped and made to pay damages. He knew people who for six years past had been infringing utterly invalid patents, and now the patentees were going to make the patents valid by a certificate of explanation, and would then attack the users of the patents and make them give up, and if the judge saw fit to decide that the original claims were framed with reasonable skill and knowledge, he could decree damages for past infringements, besides giving an injunction against the continued use of the plant erected, solely with a view of using the invalid patent, which at the date of the erection of the plant was hopelessly invalid.

The CHAIRMAN: And do you think the judge would rule that as the right interpretation of the Act?

Mr. THOMPSON said he could not help himself. He was bound to do it.

The CHAIRMAN thought such a provision ought to be altered at once, it was so palpably absurd.

Mr. THOMPSON went on to say he did not object to making the final specification agree with the provisional—he thought it should do so, and the application ought to be null and void if it did not; but what he objected to was the appointment of men to decide this question who had not scientific knowledge. The Solicitor-General or Attorney-General, up to their eyes in business as they were, had no time to attend to their duties under the Act.

Mr. EUSTACE CAREY said he was not quite clear as to Mr. Thompson's view of the retrospective operation of the Act. He understood Mr. Thompson to say that if A and B had been working an old invalid patent the owner of the patent could take steps for enforcing the validity of it. No doubt from that date A and B would have to pay royalties for the use of the patent, but he did not understand that they would be made liable for the time the patent had remained invalid, because for that period, practically, there had been no patent at all.

Mr. THOMPSON here referred to several clauses of the Act, which he read. No precise ruling upon the point raised appeared to be contained therein, but Mr. Thompson stated that in any case, whether damages could be recovered or not for the use of a patent during a period of invalidity, a patentee after making his patent right could stop its further use, and in such a case it might be that a manufacturer's plant would be stopped and rendered useless.

Mr. CAREY: He would have to pay a reasonable royalty.

Mr. THOMPSON: He can then be prevented from working the patent altogether. You will find that in clause 45.

## Hon. Secs:

J. Carter-Bell, Bankfield, The Cliff, Higher Broughton, Manchester.

The next meeting of this Section will be held on Tuesday, February 5, 1881, at 7.30 p.m., when a paper will be read by Mr. J. von Hohenhausen on "The Separation of Benzene, Toluene, and Xylene from Crude Gas Tar, Naphtha, and Crude Benzenes." A paper will also be read by the Chairman on "A Method for the Estimation of the Isomeric Nylenes in Commercial Nylols."

MANCHESTER TECHNICAL SCHOOL, Tuesday, Jan. 8th.

MR. IVAN LEVINSTEIN IN THE CHAIR.

## GAS MAKING BY COOPER'S LIME PROCESS, WITH NOTES ON A METHOD OF GAS ANALYSIS FOR USE IN GASWORKS.

BY J. ALFRED WANKLYN.

In the course of the experiments attendant on the introduction of the Cooper lining process into gasworks, the utility of the method of gas analysis described in the *Philosophical Magazine* in the year 1881 has been illustrated in a very striking manner. Although the method has been published before, still I am encouraged by certain observations made by our chairman to offer a detailed account to the Society. As has been pointed out, there are two branches of gas analysis, which are equally logical and which are complimentary to one another. One branch of gas analysis is concerned with and measures alterations in the volume of the gas brought about by the action of reagents and by explosion. The other branch of gas-analysis is concerned with and measures the changes in reagents when they are subjected to the action of a given volume of gas. The method which I am about to describe belongs to the second branch, and consists in noting and measuring the effect on the reagent exercised by a given volume of gas.

## MEASUREMENT OF SULPHURETTED HYDROGEN IN COAL GAS.

The apparatus required is—

1. A gas bottle; capacity  $\frac{1}{10}$ th cubic foot (*vide* Fig.)
2. Indiarubber tube about 2ft. in length and about  $\frac{1}{8}$ in. interior diameter.
3. A burette divided into divisions, each division holding  $\frac{1}{10}$ oz. of water. One division of the burette, or  $\frac{1}{10}$ oz. =  $\frac{1}{100}$  gr.  $H_2S$ .
4. Narrow strips of lead paper, such as are in common use in gasworks.
5. A solution of acetate of lead made by dissolving 32 grains of crystals of acetate of lead in one pint of distilled water.

The manner of working will be easily understood. The gas bottle is first filled with the sample of coal gas by displacement, the mouth of the bottle being opened downwards and the coal gas being allowed to flow through the narrow indiarubber tube which is passed up inside the gas bottle. If the gas be passing at the standard rate—viz., 5 cubic feet an hour—it should be allowed to stream into the bottle for about two minutes. If the gas be passing at a much greater

rate, as is very often the case, an interval of one minute will be amply sufficient. The bottle having been filled with gas, and kept with its mouth pointing downwards, is then closed by means of the flask stopper, which has been charged with a measured volume of the lead solution. The bottle is then shaken twenty times, so as to cause absorption of the sulphuretted hydrogen. The liquid is then allowed to drain into the flask stopper. A testing is then made with lead paper, to ascertain whether the sulphuretted hydrogen has been completely absorbed. If requisite, more, lead solution is added, and the testing with lead paper repeated until the point of disappearance is reached. The number of measures of lead solution required to absorb the sulphuretted hydrogen must be multiplied by 10, and the resulting figure is the number of grains of sulphuretted hydrogen contained by 100 cubic feet of the gas. The capacity of the flask stopper is about 2oz. of water, and when very little lead solution is required water should be added, so as to provide a con-

venient bulk of liquid to insure good contact between the liquid and the gas when the shaking up is performed. Owing to the rapidity of the action between lead solution and sulphuretted hydrogen, and owing to the high sensitiveness of lead paper, the above-described operation is of a very satisfactory character. It is easy of execution, rapid, and accurate. By means of a regular system of testing, the exact degree of activity of the purifiers in gasworks may be ascertained, and in that manner most important information may be derived. The following testings performed at the gasworks in Tunbridge Wells may be cited by way of illustration. Number of grains of  $H_2S$  in 100 cubic feet of gas:—

Date, 1883.	Gas.	Gas after passing through Purifiers			
		No. 1.	No. 2.	No. 3.	No. 4.
29th November....	410	240	—	—	—
3rd December....	410	310	25	—	—
19th December....	410	350	110	10	—
21st December....	400	—	130	—	—
22nd December....	—	—	120	—	—
24th December....	400	—	—	—	—
26th December....	—	—	170	—	—
28th December....	450	280	100	—	—
29th December....	400	320	160	12	—

from which it follows that the work done by the different purifiers on certain days was: Grains of  $H_2S$  absorbed from 100 cubic feet of the transmitted gas by the purifiers—

29th November.....	170	..	—	..	—
3rd December.....	100	285	..	..	—
19th December.....	90	..	210	..	130
28th December.....	170	..	180	..	—
29th December.....	80	..	160	..	118

Purifier No. 1 had already been exposed to the action of gas for seven weeks on the 3rd of December, and probably at that date was as much exhausted as it can possibly become. Its persistent activity since that date is doubtless due to the revivifying action of traces of atmospheric air, which enter the gas by inevitable leakage. What may be styled the normal activity of this purifier is the power of absorbing 90 grains of  $H_2S$  from every 100 cubic feet of gas passing through it. Occasionally, as on the 28th of December, its activity suddenly springs up, owing to the entrance of a little extra air. And if we ask ourselves how much extra air must have entered to occasion the sudden rise in activity, the answer is forthcoming, viz., about 0.4 per cent. (by volume)—that is to say, one hundred volumes of the gas must have received about 0.4 volume of extra air by leakage on the 28th December. Purifiers No. 2 and No. 3 are not yet exhausted, and it will be interesting to note whether No. 2 will become absolutely inactive or whether, like No. 1, it will ultimately arrive at a condition in which it permanently absorbs 90 (or say 40) grains of sulphuretted hydrogen from every 100 cubic feet of gas passing through it.

#### MEASUREMENT OF CARBONIC ACID IN COAL GAS.

Fill the gas bottle with coal gas by displacement; add excess of baryta water in the flask stopper; shake up and allow to stand for some time; filter and wash the carbonate of baryta, which must finally be ignited and weighed. The carbonic acid is calculated from the weight of the carbonate of baryta. Multiply the weight in grains of  $CO_2$  by 1000, and the resulting figure is the amount of carbonic acid in 100 cubic feet of the coal gas.

#### MEASUREMENT OF AMMONIA IN COAL GAS.

This is best made by means of the Nessler test, if the proportion is very small. If the proportion be considerable it is best done by alkalinity. In Cooper's process of gas making, lime is employed in a manner different from that which had gone before, and with results different from that which had gone before. Up to the date of Cooper's patent lime had been used to purify coal gas after the gas had been generated in the retorts. In that manner the so-called dry lime in the modern lime purifier acts upon the gas which is passed through it; in the same manner the older milk-of-lime purifier acted; and just in the same way the oldest and most impracticable lime purifier acted, as is duly set forth in the literature of the gas industry. So far as I have been able to ascertain, the earliest mention of lime in connection with the manufacture of gas occurs in the specification of Heard, which was filed near the beginning of this century. In that specification the oldest and most impracticable modification of the lime purifiers is described. Heard used heated lime, which was carefully kept separated from the coal in the retorts, and through or over the hot lime the coal gas was allowed to pass. The method was quite impracticable, and was almost immediately superseded. Cooper's process of gas making is an entirely new departure in the gas industry. Coal pure and simple is discarded as a gas-generating material, and for it is substituted a new gas-generating material, viz., "limed coal." As may be learned from the specification, "limed coal" is

made by taking quicklime, slaking it, and thereby getting it into a state of fine division, and mixing the finely-divided slaked lime with coal. The proportions recommended are  $2\frac{1}{2}$  parts by weight of quicklime (which must be slaked) and 100 parts by weight of coal. The products arising when "limed coal" is submitted to destructive distillation in the process of gas making differs in very important particulars from products which arise when coal pure and simple is distilled.

Limed coal yields a larger fraction of its nitrogen in the form of ammonia; it also yields a slightly larger fraction of its carbon in the form of volatile compounds (tar and gas conjointly); it yields a very much smaller fraction of its sulphur in volatile forms, and the non-volatile residuum, the coke, is altered in quality, and so altered as to be improved for general purposes.

1. Experiments made in the laboratory have shown that ordinary gas coal, when limed according to Cooper's specification (instead of yielding some 6lb. of ammonia per ton of coal as in ordinary gasworks), is capable of yielding from 12lb. to 16lb. of ammonia per ton of coal carbonised. I am of opinion that, on the large scale in gasworks, an equally good result will be ultimately attained; but at present, owing to the very defective arrangement for the collection and storage of the ammonia, and also to defective mixture of the lime with the coal, a lower result has been arrived at. The utmost yield hitherto obtained on the large scale is about 9lb. of ammonia per ton of coal. But a substantial gain in ammonia, due to the liming process, has been shown by the following engineers: Mr. Trewby, at Beckett; Mr. Jones, at the Commercial Gasworks; Mr. Paterson, at Cheltenham; Mr. Wilton, at Silvertown; Mr. Eastwood, at Batley; Mr. Botley, at Wormwood Scrubs; and Mr. Dougall, at Tunbridge Wells. The highest comparative yield—i.e., the greatest difference—between the same sample of coal in its limed and its unlimed condition has been shown by Mr. Botley, at Wormwood Scrubs. Mr. Botley showed, in his experiment, that the yield of ammonia was doubled when the coal was limed. The highest absolute yield of ammonia has been shown by Mr. Dougall, at Tunbridge Wells. In the course of these trials, which have been going on during the last eighteen months, I have been strongly impressed with the inadequacy of the arrangements for the collection and storage of the gas liquor in most gasworks, and especially in old gasworks. At the old Bankside works belonging to the South Metropolitan Gas Company no gain of ammonia was registered. At the Vauxhall works, another branch of the South Metropolitan Gas Company, there was no gain of ammonia, and yet some 30,000 tons of coal had been limed. I entertain no doubt whatever that the failure to get the gain of ammonia depended on the bad arrangements which prevail at those works.

2. The slight increase in the fraction of the carbon, which assumes the volatile condition when limed coal is distilled, has been dealt with on a recent occasion, and I will pass it over without further mention.

3. The great diminution of the fraction of the sulphur, which assumes the volatile condition when limed coal is distilled, will now engage our attention. Chemists are quite familiar with the fact that sulphur present in organic compounds can be caused to attach itself firmly to calcium by simply heating the organic compound with lime; and in accordance with general chemical principles a perfect mixture of coal with excess of lime cannot possibly evolve volatile sulphur compounds when it is heated strongly. It will therefore be intelligible that limed coal should yield little or no volatile sulphur compounds when it is employed in gas making. In a preliminary experiment, in which

gas was made from limed coal, in the laboratory, so striking was the absence of sulphur compounds from the gas that the patentee recognised the gas as being fragrant rather than fetid, as is the case with common crude gas. Sulphur, as is well known, occurs in coal gas partly and mainly in the form of sulphuretted hydrogen and partly in the form of what is by gas managers termed "sulphur" or "sulphur compounds other than sulphuretted hydrogen." These sulphur compounds consist of bisulphuret of carbon and a variety of other volatile sulphur compounds which are little understood. As has been said, the main portion of the sulphur exists as sulphuretted hydrogen. I have found from 0·8 to 1·5 volume of sulphuretted hydrogen in different samples of common coal gas. The "sulphur other than sulphuretted hydrogen" in common crude coal gas, so far as I have been able to ascertain, is less than 0·3 volume per 100 volumes of gas. Both the sulphuretted hydrogen and the "sulphur compounds other than sulphuretted hydrogen" are destroyed by the application of Cooper's process, even when Cooper's process is very imperfectly carried out—that is to say, when the mixing of the lime with the coal is very imperfect the diminution of the sulphur in the crude gas has been observed. Thus, for instance, at the Vauxhall Gasworks, where the coal had been very imperfectly limed, the following observations were recorded in January, 1883:

VOLUMES OF SULPHURETTED HYDROGEN IN 100  
VOLUMES OF CRUDE GAS FROM

	Limed Coal.	Unlimed Coal
Experiment I.....	0·12	0·61
Experiment II.....	0·45	0·61
Experiment III.....	0·12	0·58
Mean.....	0·13	0·60

In addition to the evidence of a diminution of  $H_2S$  afforded by examination of the gas itself, there is other and equally conclusive evidence afforded by the prolongation of the time during which purifiers retain their activity. Thus at Tunbridge Wells the duration of the active life of an oxide of iron purifier has extended so that a life of ten days has been prolonged to much more than fifty days. In fine, the diminution of the sulphuretted hydrogen by Cooper's process is so palpable that it cannot be overlooked. Equally certain is the diminution of the "sulphur compounds other than sulphuretted hydrogen," and the diminution is palpable even in cases where the mixing of lime and coal has been very imperfect.

At the Vauxhall Gasworks there were in the early part of last year supplies of crude gas from limed coal in one retort-house and of crude gas from unlimed coal in another retort-house. Comparative testings of the gas were made, with the following results:—

1883.	Limed.	Unlimed.

13th January.....	III. 13·0	21·0
13th January.....	IV. 10·3	19·1
13th January.....	V. 10·6	—

On the 14th February, 1883, all three retort-houses at Vauxhall were placed under Cooper's system, and there was no gas from unlimed coal at the Vauxhall works, and the comparative testing came naturally to an end. In the above investigation the circumstances of the case precluded the employment of the referee's method, and Harcourt's method had to be resorted to. Each figure in the above statement is the mean of four or five readings. After the 15th February, when all the gas at the works was made from Cooper's limed coal, a pipe from the main in one of the retort-houses was caused to carry a portion of the crude gas to a small condenser, and then the gas went through a scrubber, and then through three boxes charged only with oxide of iron, and then it was collected in a small holder which was filled every day. The gas was tested by the referee's method, and gave the following results:—

1883.	Grains of S per 100 cubic feet of Gas.
20th February.....	11·8
21st February.....	13·5
22nd February.....	12·2
23rd February.....	13·2
24th February.....	13·6

On 26th February very little lime was added to the coal; next day no lime was mixed with the coal, and Cooper's process was stopped till 5th March, when it was recommenced and continued for many weeks. Continuing the tabular statement, the figures were as follows:—

28th February.....	21·5
1st March.....	31·0
3rd March.....	18·2
6th March.....	24·4
7th March.....	12·1
8th March.....	8·0
10th March.....	3·3

The amount of coal carbonised at that time at Vauxhall amounted to about 3,000 tons a week, and the success of the Cooper process was so manifest that even the officials of the South Metropolitan Gas Company were moved; and on March 9th, on the occasion of the emptying of one of the large lime purifiers at the Vauxhall works, the opportunity was seized to substitute oxide of iron for the lime. About a week later, a second lime purifier was refilled with oxide of iron; and on March 24th a third lime purifier was charged with oxide of iron, and from that time forward, for a considerable period, no lime other than that employed in the Cooper process was used at Vauxhall. As I have already mentioned, the liming of coal as carried out at Vauxhall was very irregular and imperfect. Since that time the Cooper process has been put in operation under less unfavourable conditions.

By the aid of the admirable machine which the gas industry owes to the eminent and accomplished engineer whose services the Corporation of Manchester are about to lose, a good and regular admixture of the lime with the coal has become practicable. And at the Tunbridge Wells Gasworks—notwithstanding that the coal is rather highly sulphurous, containing 17 per cent. of sulphur—an average of 3 grains of sulphur per 100 cubic feet of gas has been maintained for three weeks. Not only has the lime purifier been abolished at Tunbridge Wells, but so altered is the function of the oxide of iron that the manufacture of gas in Tunbridge Wells has been correctly designated by Mr. Spice as an operation in

closed vessels. With the sulphur reduced to 3 grains per 100 cubic feet of coal gas, and with purifiers which require changing only once or twice a year, the gas industry enters upon a new era.

#### DISCUSSION.

Mr. WEST (gas engineer to the Manchester Corporation): It is a question of much importance to gas engineers as to which is the best process of purification, the one adopted by the London companies or the Cooper process. The latter process has not been adopted on a large scale throughout England, inasmuch as what can be made a success in one place cannot be achieved in another, owing to the difference in the quality of material used. The quality of the cannel and coal used in the south is of such a nature that the lime will mix with it more thoroughly than it will in Manchester. The question might arise whether the addition of the lime in the retorts is better than placing it in the purifiers for the removal of the sulphur compounds. In London they are under stricter regulations, and they have a larger number of purifiers, and they use oxide of iron with lime; and although we are not subject to these restrictions in Manchester our purifying plant is very extensive, and by the adoption of the lime process we could remove the sulphur compounds. Of course we have many difficulties to contend against in a large works that they have not at Tunbridge Wells, and had it not been for these difficulties we might have been trying the Cooper process at the present time, but seeing that we have so many different kinds of cannel and coal which give different results—some a larger quantity of ammonia than others—no test would be satisfactory unless carried on on a large scale, and as gas engineers we only require some definite proof of the advantages claimed to induce us to adopt this particular process. For my own part I do not doubt but there will be some drawbacks. While there is an increase of ammonia and a reduction of the sulphur compounds, the question arises, How does it affect the coke? We are informed that in the south there is no detrimental effect, but there they have about 5 per cent. of ash, while in some of our materials we have 20 or 30 per cent., and this again increases our difficulties. By the application of lime in the retorts we should lose the sulphur, which is now taken up in the oxide purifier, and this would be a serious loss. We received £4,000 last year for spent oxide, and this would be lost if the sulphur were taken out. It was a question which was the most economical of the two systems referred to. They had been told that the Manchester gas contained from 20 to 40 grains of sulphur to 100 cubic feet of gas, but he did not attach much importance to that. It was published in the gas committee's reports annually, and it varied considerably every day on account of the different qualities of material used. In reference to the complaints made as to the danger to health and the injury done to books and other articles, we have the evidence of Drs. Russell and Ogden, of the South Metropolitan Gasworks, that these impurities are not so injurious as they are made out to be, and it has been proved that the damage done to the books in the London libraries was caused by heat from a flue, and the destruction which is attributed to the impurities of the gas may be traced to similar causes. The purification of gas is a question of pounds, shillings, and pence, and we as gas engineers are willing to remove the impurities if the public will pay the cost.

Mr. HUNTER (gas engineer to the Salford Corporation): The difference in the percentage of sulphur in the Manchester and Salford gas, as compared with London, was to be accounted for in a measure from

the fact that the London companies had the best known process of purification, but the plant in other respects was very similar. I do not know exactly whether Professor Wanklyn gave us figures for comparison, but I think we should take the best known methods of abstracting these impurities. Will Prof. Wanklyn kindly tell us now what method of comparison he employed?

Professor WANKLYN: During the time the gas was limed at Vauxhall the result was very much the same as that obtained by the most perfect system of lime purification, and when this system is resorted to they can reduce the sulphur to something like 12 grains, but we profess to keep it down to 2 or 3 grains, and we have done this in retort-houses carbonising 3,000 tons of coal.

Mr. HUNTER: I think that puts it very clearly. First, we have the old method of purification by oxide and lime or the two combined, the second is the one adopted by the London companies, and the third is that advocated by Professor Wanklyn. In the two last processes the sulphur impurities are very much the same, but in justice to the Cooper process we are bound to admit there is an increase in the amount of ammonia and the volume of gas produced. With regard to the experiments in Salford, whether we did our duty or not, or dealt with the matter in an imperfect manner, I am not prepared to say, but we did not obtain satisfactory results. We had an increased amount of ammonia, and the purifying boxes ran longer, but we did not obtain an increased volume of gas. While admitting these two advantages, the addition of moisture to the dry coal seemed to be detrimental to the yield of gas, notwithstanding the professor told me that 2½ per cent. of lime moistened did not make any difference in the yield of gas; and taking this into consideration there is not very much to be gained by the process—in fact, it is more a loss than a gain. Our manner of dealing with it may be different to that carried on at Tunbridge Wells, but every facility was offered to the professor in making the experiments. I think there is much needless alarm as to the impurities in gas, and I believe it is impossible to prove they are injurious to health or materials.

Mr. R. F. CARPENTER said he would like to know whether there was any loss of illuminating power by the application of the Cooper process? Could Professor Wanklyn also say how the sulphur was combined with the lime in the coke, as sulphide of calcium was liable to give off sulphuretted hydrogen, and how would the moisture used for slaking the coke affect this?

Mr. H. GRIMSHAW: My first acquaintance of the large amount of sulphur in the gas was in finding drops of vitriol on my globes and the damage done to my books by the sulphuric acid. I think these impurities might be got rid of by utilising the gas profits, which at present were appropriated by the Corporation for street improvements, in the adoption of one of the processes for purification which had been referred to. I should like to know what was the effect of the lime on the coke as a commercial article, and what are the respective quantities of lime used in the Cooper process and the ordinary lime-purification process.

Mr. MELLOR: It has been stated that there was something like 40 grains of sulphur in the Manchester gas, and Professor Roscoe said some time ago that experiments made at The Owens College gave 27 grains. It was very desirable to know what were the facts. With different kinds of coal the result must vary.

Mr. SCUDDER: I made the experiments at Salford and found that the addition of slaked lime lowered

the temperature so much that the yield of gas was reduced from 9,000 to 8,700 cubic feet. When it was drawn from the retort the water from the coke was found to contain sulphide of calcium. I cannot concur in Professor Wanklyn's statement that in the use of lime the coke was not deteriorated. Two or three per cent. of lime, in addition to the amount of sulphur arrested—say, about 5 per cent.—added to the already large amount of ash, is a serious matter. I have made many experiments on the amount of sulphur in Salford gas, and the lowest result has been 24 grains of sulphur to 100 cubic feet of gas.

Mr. WATSON SMITH: We have tested the gas at the Owens College during the last few days, and the result has been 31 grains of sulphur in 100 cubic feet of gas.

Mr. GEORGE E. DAVIS: I simply rise, Mr. Chairman, to enter my protest against the statements which have fallen from the lips of the gas engineers this evening, that there has been much needless alarm as to the sulphur impurities in gas. I wish to say that, as yet, we, as householders, are not sufficiently alive to the very deleterious effects of this sulphur impurity. The Government has long ago recognised the dangers to which it may be subjected from this source, and has limited the amount which the London companies may not exceed, except under heavy penalties. The Government also, recognising the danger of allowing an unlimited escape of sulphurous acid into the outside air, has legislated in this direction also, so that manufacturers are not allowed to emit above a certain quantity of acid gases, sulphurous acid being one of them.

#### REPLY.

Prof. WANKLYN: If I may be allowed, at this late hour, I shall omit to reply to several of the questions which have been asked. With regard to the cost I have gone very carefully into the figures, and an eminent gas engineer has examined them, and he assures me that the statement is very favourable to the Cooper process. As to the question of the condition of sulphur in coke, no doubt some of it exists as sulphide of calcium, but there is some free lime also, and it is very probable that lime and sulphur may exist side by side. The quantity of lime used in the Cooper process is barely equal to the sulphur. It has been stated that the coke is damaged by reason of the lime mixed with it, and that the coke so used in furnaces is liable to destroy them, but I have had experience on over 30,000 tons of coal with the liming process, and I have found but little damage to furnaces in using this coke. It is certain that difficulties may arise in the practical application of the Cooper process, as every works is carried on in a slightly different manner. There is no doubt much difficulty in getting workmen to believe in any new process, and it has been my experience in every case that within 24 hours after the introduction of the Cooper process some difficulty has been found to exist. In works where the workmen are well looked after, and the manager interests himself in the process, these difficulties are soon overcome, but in other cases, where the workmen are left to their own resources, the process is condemned at once. In Salford I am not surprised that the results were not quite so favourable as at Tunbridge Wells, as the coal was used in large lumps, and a perfect admixture of the lime with it was practically an impossibility; but where the lime can be thoroughly mixed with the coal there is no doubt that the result of the process will be satisfactory. Where the Cooper process is used, it may be said that the purification of the gas is practically accomplished, in closed vessels, for the charges in the purifiers last much longer than when used in the ordinary way, and

we have found that the use of lime purifiers can be dispensed with altogether. The small percentage of carbonic acid does not seem to have much effect in reducing the illuminating power of the gas. It seems to be the opinion of the eminent gas engineers we have present this evening that the presence of the sulphur compounds in the gas is in no wise detrimental to health. When I first studied the subject I was inclined to think that the small amount of sulphur was a very slight matter, but I think differently now, especially as I have found that the quantity may be easily reduced to below 10 grains per 100 cubic feet, and I am sure everyone will agree with me that it is the duty of gas manufacturers to supply as pure an article as possible. The atmosphere of the underground railway in London is simply unbearable on account of the sulphurous acid which is mixed with it.

Meetings—Session 1884.

February 7th, 1884.

March 6th, 1884.

## GENERAL MEETING AT THE COLLEGE OF SCIENCE, NEWCASTLE, January 10th, 1884.

MR. B. S. PROCTOR IN THE CHAIR.

The CHAIRMAN: As usual at this meeting, we have gathered together a collection of apparatus, etc., for the inspection of the members, but we have in the first place a very important matter to discuss. The letter of Dr. Lunge, published in the report of the meeting of the Liverpool Section, in the Journal for November, has raised the question of international methods of sampling and testing commercial products, and the Sections have been invited by the Council of the Society to discuss the desirability and practicability of establishing such international agreement on methods of sampling and testing. I believe that we are all agreed that the discrepancies which frequently occur amongst the reports of different analysts testing the same substance is a wrong thing, and we are agreed also as to the importance of taking steps to remove such a state of things. I believe, however, that this can only be accomplished in the lapse of a long course of time, and I doubt whether at present we are able to do much in the matter beyond endeavouring to obtain a full expression of opinion from all those concerned. The discussion at Liverpool has already brought to light many instances of widely-differing results got from different methods of testing the same substance, and several expressions of opinion that the contract notes between buyer and seller should state by what mode of testing the value was to be determined. If a committee was appointed no doubt its first duty would be to gather from different trades and different districts information as to how far these expressions of opinion at the Liverpool meeting were supported. The decision of such a committee would soon acquire very considerable influence, and in all probability would ultimately have the authority of an umpire in all disputed cases. I have

no doubt that to-night we shall have further illustrations of the difficulties and inconveniences which our present want of system causes in many industries. Mr. Pattinson has promised to open the discussion with a short paper, which I will now call upon him to read.

## INTERNATIONAL METHODS OF SAMPLING AND TESTING.

BY JOHN PATTINSON.

THE General Council of the Society of Chemical Industry, at their meeting on the 23rd of November last, passed the following resolution: "That this Council approves of and adopts the resolution of the Liverpool Section upon methods of international sampling and testing, and recommends it to the consideration of the various local Sections of this Society, with the view of eliciting an expression of their opinion upon this important subject." It is in accordance with this recommendation that the matter is brought before your notice this evening, and I have undertaken to open the discussion by a short paper.

As those of you who have read the Society's Journal for November last are aware, this question of attempting to bring about an international agreement as to methods of sampling and analysing ores, raw products, and chemicals was first brought forward by Professor Lunge, of Zurich, at the suggestion of the German Society for the Promotion of Chemical Industry. Dr. Lunge addressed a circular letter, the purport of which has already appeared in the Journal, to the representatives of the most important chemical industries, and to commercial analysts, in England, Germany, and France. It does not indicate a widespread desire for change in the present state of things, nor augur well for the chances of success of any scheme for effecting an international agreement, that only 10 replies were received to the 40 letters sent to England, 3 to the 43 sent to Germany, and 7 to the 43 sent to France, or 20 replies to the 126 inquiries. It is obvious that any attempt to produce uniformity in these matters, in order to be successful, should secure the general adhesion of the parties most concerned in the various countries.

I think most of us will admit that in the abstract, for the purposes of facilitating calculations and of avoiding misunderstandings, it is desirable to have an international agreement as to uniform methods of analysis for determining the commercial value of products, and as to uniform methods of expressing the results of analysis. It is, for instance, desirable that methods of analysis should be used by which the same sample of manure wherever tested should indicate the same amount of soluble phosphoric acid, and that a unit of soda, chlorine, iron, manganese, lead, or copper should mean the same thing in all countries.

It is on the questions of how far it is desirable and how far it is practicable to bring about an international agreement on these matters that there will be differences of opinion. When it is considered that in some trades there are usages in the matter of analysis, to alter which would probably seriously reduce the value of the commodities, and when it is remembered that analysts have their own prejudices and predilections in favour of certain methods of analysis they are in the habit of using, and which they would be unwilling to give up in favour of methods which they believe would give less correct results, it will be seen that there are many difficulties in the way of arriving at uniform international methods of analysis.

In the purchase of copper ore, for instance, it is a

"trade" custom to determine the amount of copper these ores contain by what is known as the Cornish assay. It is well known that this assay does not indicate the whole of the copper the ore contains, and that it is moreover very irregular and uncertain in its results. Will the committee which may be appointed on the question decide that in future all copper ores should be analysed by methods which are known to give exact and uniform results? And, if so, will all the copper smelters agree to purchase by the method prescribed by the committee? Again, in the chief chemical industry of the kingdom, and one in which this district is largely interested—the soda trade—there are some trade usages which prevail in the mode of testing and of stating results, all of which affect the commercial value of the commodity. For instance, from the earliest period in which the Le Blanc process of making soda has been carried on in England it has been the custom of soda manufacturers to sell soda for commercial purposes by what is known as the English test. This test is based on what was at one time thought to be the true combining weight of soda, viz., 32, by which pure carbonate of soda is assumed to contain 59½ per cent. of soda. It is now considered that 31 is the true combining weight, and that pure carbonate of soda contains 58½ per cent. of soda. This is a custom perfectly well known by both buyer and seller, and alkalimetric tables showing the relation of the English test to other modes of testing are in almost every handbook of chemistry and chemical analysis in the English language. It cannot, therefore, be said that any purchaser is misled or deceived by the test. It is easy to see why the change from the old-established mode of testing to the more theoretically correct new one has never been made in this large trade. To do so, at one time, when soda was more valuable than it is at present, meant reducing the price of soda ash by four or six shillings per ton, and at present would mean a reduction of two or three shillings per ton in the value. Will the proposed committee decide that the English soda makers must henceforward sell by the more theoretically correct test? If so, can the soda makers recoup themselves for the change by increasing the price of soda ash? I know some soda makers think this is impossible. If this is the case, are the soda makers likely to agree to reduce the value of their product in this manner, at a time when their trade is depressed and struggling for existence? Under these circumstances, is it likely that all commercial analysts will fall in with the recommendations of the committee and test by the new international method?

There is another trade usage in connection with the testing of soda ash which should be dealt with by any committee which may be formed. I mean that relating to fractions of percentages. It is the custom to buy and sell soda ash by whole units, and to discard fractions. At one time it was the custom to discard all fractions of units, so that a soda ash of 51.9 per cent. of soda was bought and sold as only 51 per cent. More recently it has been the practice of commercial analysts in Liverpool to give a certificate that a sample contains, say, 52 per cent. of soda, when the test only indicates 51.5 per cent., or any fraction above this up to 52.4 per cent. Other analysts in London certify that a sample contains, say, 51.1, 51.2, and so on as found up to 51.5 per cent. of soda; but if it contains 51.6 per cent. a certificate is given that it contains 52 per cent. It has been my practice during the last twenty-five years to show all the fractions on the certificate, and to test by the English test, stating this on the certificate, believing that the old custom of testing by the English test and that of giving away all the fractions should stand or fall to-

gether. It is desirable that this point should be dealt with in the case of any proposed change.

Before leaving the subject of soda tests I should like to refer, in passing, to Dr. Hurter's remarks made at the Liverpool meeting on the differences between what he calls the Lancashire and the Newcastle soda tests. Dr. Hurter accounts for certain differences found to exist between tests made in Liverpool and those made on the Tyne by assuming that the higher Liverpool tests were made with test acid, based upon Fisher's and Dalton's tables of equivalents, published respectively in 1802 and 1808. This is an ingenious theory, but it is not borne out by facts. Many years ago I was in correspondence with most of the analysts in Liverpool, from whose laboratories the high tests emanated, and they assured me that they tested with test acid made in the same way as my own, viz., on the assumption that pure carbonate of soda contains 59½ per cent. of soda. There is, moreover, printed evidence that so far back as 1836—ten years after the first soda works was started in Lancashire—the same test was used. The late Mr. Wm. Gossage, who has been styled the father of the English soda trade, published in the *Chemical News* of the 17th of January, 1863, a paper entitled "A Method of Assaying Rough Soda (black ash) for the use of Soda Manufacturers, arranged by W. Gossage in 1836," and which Mr. Gossage says he still continued to use in 1863. In this method the test acid is directed to be made on the assumption that 32 is the equivalent number of soda, or that pure carbonate of soda contains 59½ per cent. of soda. There is therefore no doubt that what I have described as the English test is the test which has been in use in Lancashire as well as in other parts of England almost ever since the soda manufacture has been in existence. The differences in the Liverpool and Tyne tests exist, although there is, and has been, a theoretical agreement as to the method of testing, and the same difference would probably occur even although a committee might decide to recommend another method of testing. This points to the need of a court of appeal rather than to the formation of a committee to recommend methods of analysis.

Perhaps the case in which there is most need for a defined and prescribed method of analysis is that of the estimation of phosphates in manures. This has been and still is a fruitful source of dispute. So far as my experience goes, however, the cases of dispute are not now so numerous nor the differences so great as they formerly were. This is probably partly owing to the buyers and sellers learning to know where they can get high tests and where low; or it may be, and I hope it is, owing to better methods of analysis being adopted. I do not know of many other cases in which the differences of analysis are so great and the disputes arising therefrom so numerous as to call for any special legislation from a central body.

From a commercial standpoint we see arguments of weight both for and against the adoption of international methods of analysis. However much we may think it desirable to be agreed upon methods of analysis which shall be constituted the standard methods for the respective articles of manufacture or trade to which they refer, so that in the hands of two equally-skilled chemists the same results may be obtained, we see also that there are objections to the establishment of such standard methods, which in many cases render it a very delicate question to deal with, involving the whole monetary basis on which a trade has been founded and now exists.

Apart from this merely commercial point of view, I can also see other objections to the scheme which seem to me worthy of consideration. Speaking as a scientific man, I fear that one result of prescribing

standard methods of analysis would be to limit original research. How often in the history of chemistry have methods of analysis, believed at one time to be correct, been proved by the knowledge gained from research to be inaccurate, and have had to be given up, others being adopted, which again in their turn have been abandoned? The desire of chemists should always be to seek continually for better methods of analysis. If standard methods be prescribed, it must to a very great extent remove the incentive to original research, and a class of chemists would arise who would become mechanically skilled in these methods, but who would do nothing to further our knowledge of science. I agree with Dr. Lunge in thinking that by the co-operation of manufacturers and chemists new and admittedly better methods might be adopted as standards from time to time in the place of former standard methods, provided such new methods are discovered; but what I fear under the proposed scheme is that when fixed standards have once been established the inconveniences and obstacles in the way of any further change would be so great that chemists would be contented to go on using the prescribed methods, and cease to strive after more perfect ones.

As to standard methods of sampling, I am inclined to agree with Dr. Hurter that these can only be prescribed very generally, and that in most cases it will be best to leave the sampling to the judgment of the buyers and sellers or their agents.

I attended the meeting of the London Section of this Society on Monday last, when this question was discussed, and at which the representatives of various trades were present. The general feeling seemed to be, that whilst theoretically it was desirable to have an international agreement on methods of analysis, the difficulties in the way were so great that its attainment was impracticable. Amongst other cases that of potash salts was mentioned. Mr. Allen, the reporter for the committee appointed by the British Association, some years ago, to endeavour to arrive at a uniform method of testing potash salts, stated that although a method which was supposed to give the most exact results had been recommended by the committee, yet no change had been made in the methods of analysis by which these salts were bought and sold. It was also stated that the Association of German Potash Manufacturers had recently passed a resolution to sell only by the higher tests of the German analysts. Mr. Newlands mentioned at the meeting a method adopted in the sugar trade for settling any differences arising from analysis. Sugar is bought and sold on the arrangement that if the analyses of buyer and seller differ to a certain amount the sample is sent to an agreed umpire, whose decision is final. I venture to think if this plan were adopted by the manure trade, or any other trade inconvenienced by the differences found in analyses, the disputes would be satisfactorily settled, and the differences arising from different methods of analysis would very soon disappear.

From what I have said above it will be seen that unless the functions of any committee which may be appointed to deal with this subject are carried out with great care and judgment more harm than good may result from any attempts to change the present state of things. I am disposed to think, however, that in a Society like ours, including in its members many manufacturers and consumers of chemicals, as well as analysts and commercial men, a committee may be formed, into whose hands this matter may be safely placed. This committee should endeavour to decide in what cases, if any, and under what circumstances, it is desirable to take action, with a view to

obtain international uniformity, and report to a general meeting of the Society, and I am prepared to move a resolution to this effect.

Mr. Pattinson then moved the following resolution, which was seconded by Mr. W. W. Proctor: "That the Newcastle Section recommends the General Council to appoint from the members of this Society a committee composed of chemical manufacturers, consumers, and analysts, whose duty it shall be to determine in what cases, if any, it is desirable to endeavour to obtain national or international agreement on chemical questions affecting the value of chemical products, and to report to a future meeting of the Society."

#### DISCUSSION.

The CHAIRMAN: Mr. Pattinson has set before us very efficiently the difficulties which lie in the way of international agreement; still we should not regard these difficulties, without further discussion, as insuperable. I am inclined to think that in many cases, if buyer and seller were to adopt the practice which Mr. Pattinson has instanced as holding in the sugar manufacture, of stating in the contract the method of analysis to be used, and in the event of disagreement between the analysts referring the matter to the final decision of an umpire, these differences would in the natural course of things gradually disappear.

Mr. JOHN MORRISON: I believe the manure trade is the one which suffers most at present from analytical discrepancies. But there are great difficulties in the way of introducing new methods, or uniformity of method, for the relations amongst chemists, manufacturers, and buyers and sellers would for a time at any rate be upset. At present, for instance, London tests are, as a rule, higher than provincial results, and it would be difficult to get manufacturers to agree to any lower tests, for selling at any rate. In the soda trade the matter is not so serious. Errors exist, and the difference between the Liverpool and the Tyne tests, for instance, is a thing which none seems ever able clearly to understand or explain; but here the discrepancies are tolerably uniform, and can be allowed for. I believe, however, that a standard method of sampling should be enforced, for I know that sampling is frequently done at present in an extremely loose manner. In the soda trade you, as a rule, buy and sell by the actual tests of the analyst's sample; but in the manure trade you guarantee a certain percentage, and practically, in order to allow for possible differences of analysis and of irregular sampling, you have to make your goods up to something considerably over the guaranteed strength. This is another source of irregular loss to the manufacturer.

Mr. MOULT (Langdale's Chemical Manure Company Limited): This subject has been often discussed by the Manure Makers' Association, but nothing definite has come of it. We have had interviews with Dr. Voelcker and other London analysts; and by some of the manufacturers it has been suggested that we should fix a method of analysis, and buy and sell only by that method. At present we do not know what method is used in an analysis, but we get to know gradually, if we send samples to a certain chemist, how his results will come out. The differences are not nearly so great as formerly, but still there are differences of as much as  $\frac{1}{2}$  per cent. of phosphoric acid in an ordinary 25 to 30 per cent. soluble superphosphate. I endorse Mr. Pattinson's resolution, but I certainly think it would be desirable to have fixed methods of analysis, as far as possible, for commercial purposes.

Mr. JOHN GLOVER: I do not know that I can add much to what has been said. I am in favour of

Mr. Pattinson's resolution. I do not think that there would be so much danger of stereotyped modes of thinking, etc., of stoppage of original research, from the adoption of fixed methods of analysis, as he seems to fear. I do not see why that should happen in analytical chemistry more than in any other science. In my opinion the chief difficulty in the way is in educating merchants and manufacturers to see the advisability of fixed methods of analysis. If Associations like the Iron and Steel Institute, the Manure Makers' Association, and Alkali Association could be brought to see the necessity for a fixed method, then the Scientific Societies, the Chemical Society, the Institute, and this Society would be able to advise them as to the choice of the best method in each case. If only there is a call from the great majority of buyers and sellers for the best method of testing in any particular case the objections of individuals to the method will have to stand aside. I have often found differences in analyses (especially in alkali and bleach testing) explained by attention and value being given to the moisture in the sample at the time of weighing. As regards sampling, I would point out that much loss is often caused to buyers of ores, such as pyrites, manganese, etc., through the unavoidable drying of the sample by the heat engendered in the breaking up and pounding necessary to obtain it.

Mr. STARK: I quite agree with Mr. Pattinson's proposal of a committee to consider the matter. The first step must be to get a clear statement of what it may be considered desirable to do, and to fully discuss the difficulties in the way. On the question of sampling there must always be a good deal of liberty and discussion allowed. Any attempt to draw a hard and fast line would lead, I am convinced, only to further difficulties.

Mr. DAVIDSON: I came here to-night, not with the intention of offering any remarks, but of obtaining, if possible, some satisfactory explanation of a matter which from time to time has perplexed me, viz., the great difference which exists between the Lancashire and Tyne tests of soda ash. I have listened carefully to the excellent paper read by Mr. John Pattinson, and the solution which I seek seems to be more remote than ever. That gentleman stated in the course of his remarks that in the testing of soda ash, the test acid used both by Lancashire and Tyne chemists was prepared on the assumption that carbonate of soda contains 59 $\frac{1}{2}$  per cent. of soda. Mr. Glover observes that though this basis is not strictly accurate, yet as it is universally observed the error will be uniform, and therefore no injustice can arise. But, sir, I assure you that the error is far from uniform. There is a difference between the results of Lancashire and Tyne chemists of from one-half to three per cent. I have divided sealed samples of soda ash into two portions, and received certificates to the following effect:—

1. 48 per cent. soda by Lancashire test.
2. 48 per cent. soda by Lancashire test.
1. 45 $\frac{1}{2}$  per cent. soda by Tyne test.
2. 46 $\frac{1}{2}$  per cent. soda by Tyne test.

Now, sir, in view of the method of analysis being a standard one, and the operation to be performed a very simple one, it is difficult to understand the great want of uniformity in results. No doubt the court of appeal suggested by Mr. Pattinson would be most useful. Its usefulness would also be enhanced had it the power to reprimand chemists whose results were proved conclusively to be inaccurate.

Mr. JOHN PATTINSON: I think the remarks of Mr. Davidson fully bear out the position which I took—that it is of little use merely having a method of analysis stated. We have that in the soda trade, yet

these differences between Tyne and Lancashire tests always occur. The methods for phosphoric acid, too, are well described in the books, yet differences arise between chemists using the same method. Besides stating the method of analysis, we must have courts of appeal in case of differences.

Mr. T. W. Hogg: The question affects all industries. It would be very desirable to have a fixed method of sampling pig iron, for example, because different parts of the same ingot differ in their composition.

Mr. H. R. PROCTER: The analysis of tannins at present is in such an unsettled condition that an analysis is useless unless the method is stated. I do not know whether it will be possible to get at an agreement, but I believe the German chemists have a commission at present investigating the matter, though I do not know whether they have yet come to any result. In the case of tannins, I think the way out of the difficulty will be to state the method of analysis in the contract rather than to lay down any one method.

Mr. S. DUNN (West Ham, London): I think it would be most desirable always to have the method stated, otherwise the difficulties in comparing results are very great. In acetic acid, for instance, in which I am interested, the results of different methods may vary to the extent of 8 or 10 per cent. Such a state of things wants a remedy, and the method proposed is a step likely to lead towards that.

Mr. W. W. PROCTOR: The resolution, if carried, will do much good in promoting discussion. I think the question of sampling is of quite as great importance as that of testing.

Dr. H. S. PATTINSON: The ventilation of opinion on the matter must do good, and it will, at any rate, be pointed out in what directions new or improved methods are wanted.

The resolution was then carried unanimously.

Afterwards Mr. H. R. Procter exhibited the method of determining the electro-motive force of a battery. Mr. T. W. Hogg exhibited some Sprengel specific gravity tubes, an improved gas regulator, a modification of Carmichael's apparatus for upward filtration, and an improved valve for a wash-bottle. Messrs. Mawson and Swan showed Stead's gas apparatus, gas sampler, and chronometer for determinations of carbon in iron and steel.

## Communications.

### SECTION FOR GLASGOW AND THE WEST OF SCOTLAND.

A NUMEROUSLY-attended meeting of gentlemen desiring the formation of a Glasgow and West of Scotland Section of the Society of Chemical Industry was held at the rooms of the Religious Institution, Glasgow, on the 8th of January. Professor Ferguson, of the University of Glasgow, was called to the chair. Dr. Dobbie read letters, apologising for inability to attend the meeting, from Mr. Crum, M.P., Mr. James White (of Overtown), Mr. James Maclear, Mr. Kirkpatrick, Dr. A. P. Aitken, Mr. Ivison Macadam, Dr. Falconer King, Mr. Robert Irvine, and Mr. D. Harris. Dr. Dobbie then read a requisition, signed by thirty-two members of the Society resident in the West of Scotland, asking the Council of the Society to sanction the formation of a Section having its centre at Glasgow. Mr. Stanford then moved: "That a Local Section of the Society of Chemical Industry be formed in Glasgow, to be called the Section for Glasgow and

the West of Scotland." This motion was seconded by Dr. Dobbie, and carried unanimously. On the motion of Mr. Alexander Whitelaw a committee was then appointed, consisting of Professors Ferguson, Mills, and Dittmar, Dr. Wallace, Dr. Clark, Mr. James Maclear, Mr. R. R. Tatlock, Mr. J. F. Rowan, Mr. J. B. Readman, Mr. J. Christie, Mr. T. L. Paterson, Mr. George MacRoberts, Mr. George Beilby, Mr. J. J. Coleman (treasurer), and Dr. Dobbie (secretary). At a meeting of this committee which was subsequently held, Mr. E. C. Stanford was elected chairman of the Section, and Professor Ferguson vice-chairman. The first meeting of the new Section will be held on the 7th February. The Section already includes nearly all the leading chemists of the West of Scotland. Plenty of papers are already promised it, and it has every prospect of a most prosperous career.

### A REVIEW OF THE PRESENT METHODS OF PREPARING HYDROBROMIC ACID, AND A DESCRIPTION OF A PROCESS FOR PREPARING IT FROM BROMIDE OF ZINC AND SULPHURIC ACID.

BY AD. SOMMER, SAN FRANCISCO.

THE methods recommended for preparing hydrobromic acid may be grouped into four classes: (1) Direct combination of bromine and hydrogen, (2) Decomposition of hydrogen compounds by bromine, (3) Decomposition of the compounds of bromine with the solid metalloids by the action of water, (4) Decomposition of metallic bromides by acids.

FIRST CLASS (direct combination of bromine and hydrogen): Br and H do not combine at ordinary temperatures, not even under the influence of direct sunlight. To effect their union an elevated temperature is necessary. (a) Br and H are brought in contact with a Pt wire, kept at red heat by the electric current. (b) Br and H are passed over warmed Pt sponge. (c) Br and H are passed through a red hot platinum tube. (d) Br and H are brought in contact with a flame or the electric spark. The writer has had no personal experience of any of these processes, but according to the statements of other experimenters these methods are, although the simplest in theory, the most difficult in practice. For, on account of the corrosive action of the compounds, the apparatus can only be made of glass, porcelain, soapstone, or platinum; and to make the joints so tight that neither Br nor HBr can escape is almost impossible. The product is in all cases contaminated with Br, unless the latter be removed by passing the gaseous acid over either phosphorus or antimony. An elaborate apparatus, wherein the union of Br and H is effected by their passage through a red-hot Pt tube, has been devised by Mr. A. Harding, at Berkeley, Cal., where it has been employed at the laboratory of the University of California in preparing a fuming solution of HBr containing 65 per cent. and over of HBr. (See "New Remedies," 1882, p. 43.) Wherever a pure anhydrous acid is required these methods are preferable to all others.

SECOND CLASS (decomposition of hydrogen compounds by bromine): Bromine separates hydrogen from most hydrogen compounds, notably from hydrogen-phosphide, hydrogen-sulphide, hydrogen-iodide, ammonia, volatile oils, fixed oils, resins, alcohol, ether, etc. Under the influence of direct sunlight bromine gradually liberates oxygen from water, and forms HBr. When the mixture of bromine and water is brought in contact with substances which have an affinity for oxygen, such as sulphurous acid, arsenious acid, metals, etc., the

formation of the HBr goes on rapidly. (a) Hydrogen-sulphide is passed into a mixture of bromine and water. When little water and much bromine are employed, gaseous HBr escapes, and is conducted into water. The aqueous solution of HBr so produced is then boiled until it no longer smells of  $\text{H}_2\text{S}$ . When much water and comparatively little Br are employed, an aqueous solution of HBr is formed at once. In both cases bromide of sulphur is formed simultaneously with HBr and must be decomposed by boiling, whereby free sulphur, sulphuric acid, and an additional quantity of HBr are produced. Unless further purified the products are always more or less contaminated by one or more of the following substances: Br,  $\text{H}_2\text{S}$ ,  $\text{H}_2\text{SO}_4$ . (b) Hydrogen sulphide is passed into a solution of bromine in bisulphide of carbon covered by a layer of water. HBr is formed from the Br and  $\text{H}_2\text{S}$ , and absorbed by the water, while the liberated S is retained by the  $\text{CS}_2$ . The watery solution of HBr has to be boiled in order to free it from  $\text{H}_2\text{S}$  and  $\text{CS}_2$ , but it, too, contains  $\text{H}_2\text{SO}_4$ . (c) Bromine is passed into paraffin, which is kept at  $185^\circ\text{C}$ . One half of the Br forms bromine derivatives of the paraffin, while the other unites with the H liberated to form HBr. By continuing the heat the brominised paraffin is again split up, yielding an additional amount of HBr. (d) Bromine is mixed with sulphite or thiosulphate of sodium and a small quantity of water. Here the water is decomposed, and sulphate of sodium and HBr are formed. The HBr escapes and is conducted into water. When the evolution of HBr slackens, heat is applied. A considerable portion of HBr is, however, retained by the saline mass, and cannot be conveniently recovered. The principal objection to all of these methods is their wastefulness in material. In (a) and (b) the quantity of  $\text{H}_2\text{S}$  that has to be generated, in order to effect the conversion of the Br into HBr, is many times larger than theory would indicate, since most of it passes into the air. In methods (c) and (d), on the other hand, the yield of HBr does not correspond to the amount of Br employed, because a considerable portion of Br is retained by the residues.

**THIRD CLASS** (decomposition of compounds of bromine with solid metalloids by the action of water): Bromine unites readily with some of the solid metalloids, notably with arsenic, sulphur, antimony, and phosphorus; and these bromides, in contact with water, decompose into HBr and the hydrated oxides of the metalloids. (a) Bromide of Sulphur: A mixture of Br and S is heated with water, and thereby decomposed into HBr,  $\text{H}_2\text{S}$  and  $\text{H}_2\text{SO}_4$ . The acid is very impure and must be rectified. (b) Bromide of Antimony: *Regulus antimony* is digested with Br and the bromide decomposed by an excess of water. Antimonous oxide is precipitated, and HBr remains in solution. On distilling, however, traces of Sb will appear in the distillate. (c) Bromide of Phosphorus: Bromine is gradually introduced into a mixture of phosphorus and water, or phosphorus and ice, which mixture is kept cool by means of water or ice. Either common P or the red variety may be used.  $\text{PBr}_3$  is first formed, but decomposed as soon as it comes in contact with water into  $\text{H}_3\text{PO}_4$  and HBr. The HBr is finally separated by distillation. This process gives excellent results when carefully executed, but on account of the danger of explosion the greatest care must be exercised never to allow a large quantity of Br to come in contact with P. The writer has found the following method safe and profitable: Into a glass flask of a capacity of two gallons is poured one gallon of water. One pound of ordinary phosphorus is added to this, and the flask placed in a large basin of cold water. A globe-shaped separating funnel is, by means of a perforated stopper, fitted

into the flask in such a way that the end of its tube dips into the water contained therein. When everything is in order the funnel is lifted out, filled with bromine, and the stopcock opened just sufficient to allow about 60 drops of Br to be discharged in a minute. The funnel is then again transferred to the flask, and the Br allowed to drop in at the rate just stated. After about 4 lb. to 5 lb. of Br have been added, the flask is warmed till the mixture is colourless, then allowed to cool, the liquid portion poured off, the phosphorus rinsed with a little water, and the washings added to the first liquid. Through the mixed liquids is passed a slow current of  $\text{H}_2\text{S}$  until all As is precipitated as  $\text{As}_2\text{S}_3$ , and the supernatant liquid becomes perfectly clear. The solution is then filtered, the  $\text{As}_2\text{S}_3$  washed, the filtrate poured into a glass-stoppered tubulated retort, which is connected with a glass condenser and heated by an oil bath, and the HBr distilled off. The first portion of the distillate is rejected, since it smells strongly of  $\text{H}_2\text{S}$  and contains hardly any HBr. The odourless portion is preserved in glass-stoppered bottles. Although the principal products of the reaction between bromine, phosphorus, and water are, as already stated, HBr and  $\text{H}_3\text{PO}_4$ , there are also formed small quantities of phosphorus acid and arsenious acid. The former may be produced by the spontaneous oxidation of the P after all free Br has disappeared, while the latter is due to the presence of As in commercial P. By an experiment it was found that on distilling the mixture of acids just as it is decanted from the P the whole of the As will appear in the distillate. The treatment with  $\text{H}_2\text{S}$  became thereby necessary, and it accomplishes in this case the complete precipitation of the As in less than 12 hours. The quantity of the distillate necessarily varies with the amount of water in the mixture of acids. But if a strong acid is desired, it is only necessary to remove the first portions that distil over and are of a low specific gravity. The greater bulk of the HBr distils as a hydrate of the specific gravity 1.4804 at  $15^\circ\text{C}$  which contains 47.12 per cent. of HBr. At no time, but particularly not during distillation, should the pure HBr be allowed to come in contact with organic substances, such as cork, indiarubber, paper, etc., since these substances induce decomposition of the acid, liberating Br. The connections between the retort and condenser should therefore be made of glass only. The phosphoric acid which remains in the retort, though not pure, is a useful by-product. When carefully executed this method gives almost the theoretical yield.

**FOURTH CLASS** (decomposition of metallic bromides by acids): A great many mineral acids, as well as several organic acids, liberate HBr from metallic bromides. Those employed in practice are, sulphuric, phosphoric, and tartaric acids. Of these, however, sulphuric acid, when of considerable strength, will liberate Br along with HBr, the  $\text{H}_2\text{SO}_4$  itself being decomposed into  $\text{SO}_2$  and  $\text{H}_2\text{O}$ . A number of experiments were made by the writer for the purpose of ascertaining the highest strength of sulphuric acid that can be employed for making HBr without giving rise to the secondary products ( $\text{SO}_2$  and Br), and it was found that so far as bromide of zinc is concerned any acid containing less than 80 per cent. of  $\text{H}_2\text{SO}_4$  can be employed without danger. (a) Decomposition of potassium bromide in water by means of tartaric acid, and decanting the aqueous acid formed from the precipitated bitartrate of potassium: The product contains some undecomposed bromide of potassium as well as bitartrate. The latter may be more completely removed by the addition of alcohol, filtering, and expelling the alcohol by evaporation. The acid produced by this method is very liable to decomposition on keeping. The writer has never seen any

such acid which did not in time turn yellow. (b) Decomposition of barium-bromide by means of dilute sulphuric acid, decanting the aqueous acid and distilling: The barium-bromide required for this purpose is made either from barium-carbonate and ammonium-bromide, or from barium-sulphide and bromine. When made by the former method it necessitates, first, the production of dry  $\text{NH}_4\text{Br}$  by adding Br to ammonia-water and evaporating to dryness. The dry salt is then treated with an equivalent quantity of  $\text{BaCO}_3$ , whereby ammonium-carbonate is formed and volatilised and  $\text{BaBr}_2$  left behind. When the latter method is employed, sulphate of barium is mixed with powdered charcoal or coal tar, placed in a covered crucible and heated to bright redness for some time. The resulting sulphide of barium is then mixed with water and Br, the mixture boiled, and the solution of  $\text{BaBr}_2$  filtered off and evaporated to dryness. In order to prepare HBr from  $\text{BaBr}_2$ , a known quantity of the latter is dissolved in water, and somewhat less than the equivalent amount of  $\text{H}_2\text{SO}_4$  added. The mixture is then allowed to settle, the clear liquid decanted, the precipitate washed with water, the washings added to the liquid, and the mixed liquids distilled. On the whole, this method is a lengthy one, although the product will be pure when due attention is paid to every particular. (c) Decomposition of potassium-bromide by phosphoric acid, and separation of the HBr by distillation: The product is pure, provided the materials were so; but the cost of the phosphoric acid prevents the general application of this method. (d) Decomposition of potassium-bromide by means of sulphuric acid, allowing the potassium-sulphate to crystallise out, separating the salt from the liquid, and distilling the latter nearly to dryness: Potassium-bromide is an expensive source of Br to the retail pharmacist when he has to buy it from the wholesale dealer. To make it himself in small quantities from a solution of potassium-hydrate and Br, evaporating, igniting with charcoal, redissolving, filtering, and evaporating is both tedious and unprofitable. Often the commercial bromide of potash contains bromate, and the acid will then contain three molecules of free Br to every molecule of bromate. Another unavoidable impurity of the distillate is sulphuric acid, from which, however, it may be freed by a rectification over barium-bromide. (e) The preparation of HBr from bromide of zinc and sulphuric acid, as originated by the writer: For the sake of convenience I shall divide this process into two parts: (1) The preparation of bromide of zinc; (2) the distillation of hydrobromic acid.

#### THE PREPARATION OF BROMIDE OF ZINC.

Zinc readily dissolves in a mixture of water and Br. The dissolving action, however, goes on faster when the solution has acquired a somewhat higher specific gravity than that of ordinary bromine-water, but is retarded when the solution becomes nearly saturated with bromide of zinc. In order, therefore, to utilise this peculiarity I pour the whole quantity of Br I intend to combine with Zn into a glass flask which already contains a small quantity of water, and insert a few strips of Zn, which must protrude above the surface of the Br layer. The action soon commences and is most energetic a little above the surface of the Br. When it has once fairly started, large bubbles of a colourless gas will be seen rising from the body of the Br, the nature of which gas I have not yet determined. An increase in temperature also accompanies the reaction and it is therefore well to keep the flask in a basin of cold water, and to add only a small quantity of Zn at a time. When, after repeated additions of Zn, the aqueous layer becomes

so dense that the Zn does not readily dissolve any longer, some water is added, and the additions of Zn and water repeated so long as there is any Br left. At last, an extra piece of Zn is added, and the vessel allowed to stand for some time in a warm place. This excess of Zn serves to remove most of the impurities that are generally present in commercial Zn, and particularly those which are liable to be volatilised during the distillation of the HBr, namely, arsenic, antimony, and lead. When as much of the impurities as is possible in this way have been removed, the solution is rapidly filtered and evaporated in an evaporating dish. Towards the end of the evaporation, when a pretty good heat is required to remove the last portion of water, the dish, merely protected by a piece of wire gauze, should be placed over the direct flame and the solidifying mass constantly stirred until it begins to fuse on the edges. The now granular salt, while still hot, is transferred into tightly stoppered bottles, since it is very deliquescent. Considering the ease with which  $\text{ZnBr}_2$  can be obtained in a tolerably pure state, when compared with the difficulties encountered in the production of other bromides, and, further, the advantage it has over Br in being readily handled and safely transported, it is to be hoped that it may soon become an article of commerce. If made by the bromine manufacturer, and sold cheaply, it might be made to serve as a source for Br which would not be objectionable to the transport companies.

#### THE DISTILLATION OF HYDROBROMIC ACID.

According to the statements of several investigators, aqueous hydrobromic acid, when boiled under a pressure of 760mm., has the tendency to form a stable hydrate containing five molecules of water to every molecule of HBr, which hydrate distils at  $125^\circ\text{C}$ —that is to say, when an aqueous acid is boiled under the ordinary atmospheric pressure it will either lose water, if it contains more than five molecules of water to every molecule of HBr, or HBr if the proportion is a smaller one; and it will continue to do so until there remains a liquid containing the above proportions, which will then distil over unchanged. This, however, applies, as the writer has found, only to a pure acid. In the presence of salts, and possibly, also, in the presence of other non-volatile acids, the last portions that distil are much stronger in HBr. In my experiments I therefore sought to obtain this stable hydrate, and I believe I have found a method of doing so. I take bromide of zinc 225 parts; distilled water (including the water contained in the sulphuric acid), 180 parts; sulphuric acid (calculated as  $\text{H}_2\text{SO}_4$  without water), 196 parts. The  $\text{ZnBr}_2$  is placed in a tubulated glass-stoppered retort, the neck of which is bent at an angle of about  $90^\circ$ , and drawn out to a fine point. The water is poured on the bromide, and agitated till solution is complete. Then the sulphuric acid is added (which in this case does not liberate an appreciable amount of heat), the glass stopper is tightly inserted, and fastened by a string or wire. The body of the retort is then placed in an oil-bath, the neck inclined and dipped into an empty receiver, which is standing in a larger vessel and is surrounded by water. The oil-bath is then heated rapidly, the distillation carried on as fast as possible, and the heat only lessened when excessive bumping occurs. So long as there is a considerable amount of liquid in the retort, the operation requires scarcely any attention after the heat has once been properly regulated; but when the residue in the retort is nearly dry, and the evolution of HBr slackened, close attention must be paid lest the liquid should be drawn back and fracture the retort. As soon as the liquid rises in the narrowest terminal portion

of the neck, the receiver is removed and the retort cooled and cleaned. It was found advantageous to place the neck of the retort so far into the receiver that the small orifice would be submerged in the condensed liquid, especially towards the end of the process, when a nearly anhydrous acid passes over. There is, with proper attention, no danger from the condensed liquid being sucked back, provided the orifice is made small enough, and the surface of the retort neck to which the vapours are exposed be so protected against the cooling effect of the air that no condensation, or at least only a partial one, can take place before the vapours reach the receiver, insuring thereby a constant outward pressure of the vapour from the retort. To the distillate, which contains a considerable amount of  $\text{H}_2\text{SO}_4$ , is added  $\text{BaBr}_2$ , or  $\text{Ba}(\text{OH})_2$ , or  $\text{BaCO}_3$  in excess of the  $\text{H}_2\text{SO}_4$ , and the whole again distilled to dryness. The residue from this last operation is exhausted with water, the solution evaporated to dryness, and the  $\text{BaBr}_2$  so obtained preserved for the next operation. It might appear that the rectification over  $\text{BaBr}_2$  could be dispensed with by employing an excess of  $\text{ZnBr}_2$  in the first distillation. This, however, is not the case, since by actual experiment it was found that  $\text{H}_2\text{SO}_4$  distils over even when  $\text{ZnBr}_2$  is employed in a large excess. When equivalent quantities of  $\text{H}_2\text{SO}_4$  and  $\text{ZnBr}_2$  are employed a portion of  $\text{ZnBr}_2$  equivalent to the amount of  $\text{H}_2\text{SO}_4$  that has evaporated is left undecomposed. Since, therefore,  $\text{ZnBr}_2$  is more expensive than  $\text{H}_2\text{SO}_4$ , and no advantage is derived from employing the former in excess, it is preferable to use an excess of  $\text{H}_2\text{SO}_4$ . There is still another advantage in using at least twice the theoretical amount of sulphuric acid, namely, the fluidity of the residue in the retort. Not only is the cleansing of the retort thus greatly facilitated, and its liability of being fractured lessened, but it also enables the heat to penetrate the residual mass better and expel the last portion of  $\text{HBr}$  quicker than could be the case if, on account of an insufficient amount of  $\text{H}_2\text{SO}_4$ , a hard cake of zinc sulphate were formed at the bottom of the retort. In an experiment made according to these directions I obtained 81.7 grms. of hydrobromic acid from 56.25 grm. of  $\text{ZnBr}_2$ , 63 grms. of 78 per cent. sulphuric acid, and 31 grms. of water. The specific gravity of the acid at  $15^\circ \text{C}$  was 1.48, and its strength, determined by a standard potash solution, 47 per cent. of  $\text{HBr}$ . Hence, its molecular composition was almost exactly 1 mol.  $\text{HBr}$  to 5 mol.  $\text{H}_2\text{O}$ . It is therefore safe to express the reaction by the following equation:—

## CONVERTING SULPHIDES INTO SULPHATES BY MEANS OF NITRIC AND HYDROBROMIC ACIDS.

BY AD. SOMMER.

THE following method of converting sulphides into sulphates, although not new, I have never seen in print. Possibly it may prove of value. Sulphides, even those containing free sulphur, may be converted rapidly into sulphates by digesting them first with fuming nitric acid, and when this acid ceases to act energetically, adding repeatedly very small portions of a strong solution of hydrobromic acid. The additions of hydrobromic acid are best made through a perforated watch glass by means of a miniature funnel inserted into the opening. When the sulphides, before they are subjected to this treatment, have been reduced to an impalpable powder, their conversion into sulphates by this method can usually be accomplished in three hours.

## Journal and Patent Literature.

### II.—FUEL, GAS, AND LIGHT.

*Illumination by Gas and by Electricity in Relation to Vitiating of the Atmosphere.* M. v. Pettenkofer. *Dingl. Polyt. Jour.* 249, 391.

THE author has determined the percentage of carbonic anhydride and the temperature of the atmosphere of the Kgl. Residenz-Theater at Munich, under the condition of illumination both by gas and by electricity. The initial  $\text{CO}_2$  being 4 in 10,000, the following quantities were subsequently found, the house remaining empty:—

	Pit.	1st Tier.	2nd Tier.
After one half hour's illumination by gas...	5	11	14
After one hour's illumination by gas .....	6	10	20
After one hour's illumination by electricity	5	5	6

In a full house the  $\text{CO}_2$  increased to 23 in 10,000 with gas illumination and to 18 in 10,000 with electrical. The following determinations of temperature are also of interest:—

#### ILLUMINATION BY GAS.

##### Experiment 1.—Empty House.

May 2nd, 1883. Temperature in open air,  $11.8^\circ$ .

	Pit.	1st Tier.	3rd Tier.
Minimum .....	15.2	16.2	16.2
Maximum .....	16.5	19.1	25.1
Difference .....	1.3	3.2	9.2

##### Experiment 2.—Full House.

May 6th, 1883. Temperature in open air,  $11.5^\circ$ .

	Pit.	1st Tier.	3rd Tier.
Minimum .....	16.0	16.8	21.6
Maximum .....	22.2	23.6	29.0
Difference .....	6.2	6.8	7.4

#### ILLUMINATION BY ELECTRICITY.

##### Experiment 3.—Empty House.

May 29th, 1883. Temperature in open air,  $17.6^\circ$ .

	Pit.	1st Tier.	3rd Tier.
Minimum .....	16.6	17.2	17.6
Maximum .....	16.9	18.0	18.5
Difference .....	0.3	0.8	0.9

##### Experiment 4.—Full House.

June 10th, 1883. Temperature in open air,  $15.0^\circ$ .

	Pit.	1st Tier.	3rd Tier.
Minimum .....	17.6	18.0	18.8
Maximum .....	19.6	21.2	23.0
Difference .....	2.0	3.2	4.2

Further information on the subject is given in the *Beilage z. Ally. Zeitg.*, 1883, 177. Comp. also Fischer, *Dingl. Jour.*, 1883, 248, 375, 249, 374.—C. F. C.

*Improvements in and relating to the Manufacture of Illuminating Gas, and to the System and Apparatus Employed therefor.* H. C. Ball, Brooklyn, U.S.A. Eng. Pat. 2312, 1883.

"SLACK coal" is "exposed to the air for some time, so that a large percentage of the sulphur which exists in the coal as sulphuret of iron becomes oxidised and escapes." The coal is then washed, "as practised in making high-class coke," and it is then reduced "to an impalpable powder." This powder is then passed through a "drier and desulphuriser" (also called a "conveyor"), which is a pipe, on the outside of which is a steam-jacket, and in the inside of which is a screw. This "conveyor" is inclined, so that it may convey the powdered coal fed into it at its lower extremity into an apparatus placed at a higher level and called a "mixer." The powdered coal is dried in passing along the "conveyor," and "the sulphur which exists in it as bisulphide of iron is oxidised, and escapes as sulphurous acid," by a chimney with which the upper extremity of the "conveyor" communicates. In the "mixer," which consists of a "box within which revolves a shaft carrying a series of spirally arranged arms," the now dry powdered coal is mixed

with a certain proportion of tar. The resulting mixture is then discharged automatically into hoppers, which convey it to the retorts. The retorts are placed vertically, and the charges from the hoppers are dropped into them. The inventor claims that his process yields a gas nearly free from sulphur, of greater illuminating power than gas made in the ordinary way from the same kind of coal, that he obtains a specially hard and firm coke, that he can use cheaper forms of coal than are available for the ordinary methods of gas making, and that by his method "the labour of stoking is enormously reduced."

*Improvements in the Treatment and Utilisation of certain Waste Materials which have been used in Purifying Coal Gas.* J. Walker, Leeds. Eng. Pat. 2091, 1883.

A "SULPHO-ALKALINE LIQUOR" is obtained by lixiviating with water either fouled lime from gas purifiers, or the fouled mixture resulting from the purification of gas by means of the mixture of lime and coke-dust which the author of this invention proposed for that purpose in the specification of a previous patent. This liquor is then to be used "for making a size or soft starch paste or stiffening, by adding to it" various farinaceous substances, for unhairing hides or skins, and also, "in connection with other alkalis, for making common, fancy, and insecticide soaps." The solid residues remaining after the said lixiviation, mixed or not with the oxide of iron remaining after the sulphur of "spent oxide" has been burnt off therefrom, are to be employed for agricultural purposes.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*On Acridine.* A. Bernthsen and F. Bender. Berl. Ber. 16, 1971.

THE formula for acridine recently proposed

(Berl. Ber. 16, 1802) by the authors has led them to a new means of testing the opinions expressed (*Ann. Chem. Pharm.* 158, 265) by Gräbe and Caro regarding the constitution of soluble hydroacridine. According to the latter chemists one molecule of acridine requires one atom of hydrogen for the formation of hydroacridine, whereas the authors' experiments on hydrophenylacridine indicate a probability of two atoms of hydrogen being necessary. After unsuccessfully attempting to prepare two distinct hydroacridines, the authors ascertained by experiment how many atoms of silver one molecule of hydroacridine precipitates from a solution of silver nitrate, and, finding this number to be two, conclude that hydroacridine is formed in accordance with their theory by the addition of two atoms of hydrogen to one molecule of acridine, acridine

thus becoming hydroacridine

A. S.

*On Acridine.* O. Fischer. Berl. Ber. 16, 1820.

RIEDEL (*Ber.* 16, 1612) considers acridine an anthracene in which one of the two methyl groups uniting the two benzene residues is replaced by nitrogen. The author confirms this view on the following grounds. While investigating flavaniline in conjunction with Rudolph and

Besthorn a base of the formula  $\text{C}_{14}\text{H}_{11}\text{N}$  was described, which was obtained by the action of diphenylamine on acetic anhydride in presence of zinc chloride. The same base has since been prepared by Bernthsen (*Ber.* 16, 767) in a different manner. It bears great resemblance to acridine, and the author has no hesitation in assigning to it the name methylacridine. By comparing, e.g., the hydrochloride of acridine with the corresponding salt of the diphenylamine base, it is found most difficult to distinguish between them, both salts having the same golden-yellow colour, crystallising in plates and exhibiting the characteristic bluish-green fluorescence in dilute aqueous solutions. According to Riedel's acridine formula the formation of methylacridine from acetyldiphenylamine is easily explained. Thus—

If this hypothesis be correct, then formodiphenylamine should lead direct to the synthesis of acridine. The author intends to investigate the synthesis of acridine from diphenylamine, formic acid, and zincchloride.—D. B.

*Physiological Action of Petroleum Vapour.\** Poincaré. Journ. Pharm. Chem. 7, 290.

THE author found that an atmosphere charged with petroleum vapour, such as is respired by workpeople engaged in the petroleum industry, proved fatal to guinea pigs after periods of exposure of 1-2 years; dogs and rabbits under similar treatment manifested languor and loss of appetite. The workpeople themselves complain only of an irritation of the membranes of the nose, and headache. It is nevertheless evident that in all cases precautions should be observed, with the view to prevent as much as possible respiration of these vapours by the human subject.—C. F. C.

*Pressure Reliever for Retorts, with Hydraulic Lute.* C. Pfendel, Magdeburg. Ger. Pat. 21522, May, 1882.

THE pieces of piping A and B are placed on the condenser. A dips into the luting liquid of the receiver, B enters above the same. The upper part of both pipes is surrounded by a cup D, which is also filled with a luting liquid, and into which dips the hood C, which is

divided by a partition. When the latter stands in its lowest position the communication between A and B is interrupted, so that the gas must find its way through the liquid contained in the receiver. When, however,

the hood C is raised far enough to let the partition project from the luting liquid of the cup D, the gas has an open way through the pipe B, or otherwise through the receiver.—J. G.

#### IV.—COLOURING MATTERS AND DYES.

*A New Method of Preparing β-Naphthylamine Sulphonic Acids.* L. Landshoff. Berl. Ber. 16, 1931.

THE conversion of β-naphthol into β-naphthylamine by the action of ammonia is not complete, and is attended with the formation of β-dinaphthylamine. The author has found, by heating at 230° to 250° the sulphonic acids of β-naphthol with a mixture of lime or soda and ammoniac, together with a little water, that conversion into the β-naphthylamine compounds is complete and unaccompanied by the formation of by-products. He has further found that this reaction is dependent only on temperature and not on pressure, hence heating in sealed tubes, which has hitherto been the procedure in this conversion, is unnecessary. The resulting mono-, di-, and tri-naphthylamine sulphonic acids submitted to the diazotization, and combined with amines or phenols, yield a series of colours which in the phenol series vary between yellow, orange, and brown, in the α-naphthol series between red and bluish violet, and in the β-naphthol series between yellow and red-orange.—A. S.

*Preparation of Colouring Matters from Coal-tar Quinoline.* W. Spalteholz. Berl. Ber. 16, 1847.

ON treating quinoline with alkyl iodides and potassium hydroxide a brown basic oil is separated, consisting, according to La Coste, of mixtures of alkylised quinolines and their ammonia bases, besides small quantities of a red or reddish-purple colouring matter which differs in shade from cyanine. The author has isolated this dye from coal tar, and subjected its ethyl derivative to a minute examination. On warming ethyl iodide with an equivalent quantity of quinoline, ethylquinolineammonium iodide is obtained, besides variable quantities of a red semi-fluid product. On recrystallising the iodide from alcohol, it is obtained in yellow monoclinic prisms. By digesting the red product with ether and recrystallising the residue from dilute alcohol, rhombic prisms of unusual magnificence were obtained, possessing a fine cantharadin green lustre. In its reactions with solvents the dye behaves like cyanine, hence it was concluded that its constitution might be analogous to cyanine, only that instead of the amyl group it would contain the ethyl group. Its formation may be illustrated by the following formula, according as it is regarded as a quinoline or lepidine derivative:—

quinoline dyestuff

lepidine dyestuff

The numbers obtained on analysis were found to agree better with the lepidine dye. Hence it was thought that by subjecting lepidine to the preceding operation a larger yield of colouring matter might be obtained. The red colouring matter was not, however, formed, but only a small quantity of a blue dye, which was probably identical with the ethyl dyestuff obtained by Williams from the quinoline of cinchonine. In a recent communication (Ber. 16, 1082) Jacobsen and Reimer showed that quinaldine plays an important part in the formation of the red dye by the action of benzotrichloride on quinoline. The author therefore tried to determine whether quinaldine took part also in the formation of cyanine. On investigation this was found to be the case. Quinaldine ethiodide, when treated with the crystallisable (not the red semi-liquid) quinoline ethiodide, forms a dye which exhibits the same properties as the product obtained from coal-tar quinoline. This circumstance is a further proof of the identity of coal-tar quinoline with the artificial quinoline. Analyses show that the dyes obtained from crude quinoline and a mixture of pure quinoline and quinaldine are identical. The author is continuing this research with the view to ascertain how the condensation of quinoline ethiodide and quinaldine ethiodide is effected.—D. B.

*On the Decomposition of Rosaniline with Water.* C. Liebermann. Berl. Ber. 16, 1927.

THE author having characterised the non-nitrogenous substance obtained when magenta is heated to 270° C. with water as dioxybenzophenone (Berl. Ber. 5, 114, and 11, 1434), it seemed probable that the accompanying nitrogenous decomposition products might be derived from benzophenone, and not from a molecule containing 20 carbon atoms. The difference in degree of basicity of the two nitrogenous products was made use of in order to separate them from each other and to obtain them in a pure state. A crude mixture of the two, from which the dioxybenzophenone had been previously extracted, was dissolved in a small quantity of hydrochloric acid, and to the solution water was added as long as it produced a brown resinous precipitate (I.). After filtering, the filtrate was strongly saturated with NH<sub>3</sub>, whereby a large precipitate (II.) of pale red needles was produced. This was collected after 24 hours' standing, and the ammoniacal filtrate was neutralised with HCl, when a further precipitate (III.), very similar in appearance to the last, was largely produced. The filtrate from this again produced a slight precipitate (IV.) on the addition of NH<sub>3</sub>, which dissolved both in NH<sub>3</sub> and in HCl. Three-fourths of the original mixture made up the precipitates II. and III., and only these were further investigated. Precipitate II. was well washed with cold NH<sub>3</sub>, with hot NH<sub>3</sub>, with hot dilute KHO, and finally with water. The residue was dissolved in boiling alcohol, and after filtering off some undissolved impurity the filtrate was mixed with water and evaporated to crystallisation. An analysis of the recrystallised product led to the formula C<sub>14</sub>H<sub>14</sub>N<sub>2</sub>O, so that it may be considered as diaminohomobenzophenone

It forms colourless or pale red needles, insoluble in alkalis, but readily soluble in dilute HCl, and melting a little above 220° C. Its benzoyl derivative was prepared by heating it with six times its weight of benzoyl chloride, washing the melt with boiling water till free from benzoic acid, then with boiling alcohol, and finally crystallising the residue from glacial acetic acid. It forms nearly colourless needles, melting at 226° C. An analysis shows its formula to be that of dibenzoyldiaminohomobenzophenone

The above-mentioned precipitate III. was purified by dissolving in dilute HCl, filtering from a little resinous impurity, and reprecipitating with NH<sub>3</sub>. The precipitate thus obtained was dissolved in cold dilute KHO, reprecipitated by neutralising with acid, and, after washing with water, was crystallised from dilute

alcohol. It forms then almost colourless needles, which readily acquire a red tint. After the addition of zinc dust to its acid solution it yields colourless crystals. Its composition corresponds to the formula of an amidooxyhomo-benzophenone

Dibenzoylamidohomobenzophenone

was prepared exactly as in the case of the substance above mentioned, and obtained in the form of colourless needles, m. p. 192° C. to 193° C. It seems, therefore, that when rosaniline hydrochloride is decomposed by means of water at a high temperature, the following are among the decomposition products: Dioxibenzophenone, oxyamidohomobenzophenone, and diamidohomobenzophenone. The next higher homologue of the first and the next lower homologues of the two last are possibly also present among the products of the reaction, and the same appears to be the case with rosolic acid. Owing to the great similarity of their properties and their solubility it will, however, be very difficult to succeed in isolating them.—J. J. H.

*Paranitrobenzaldehyde and Acetone.* Ad. Baeyer and Paul Becker. *Ber. Ber.* 16, 1968.

WHEN benzaldehyde and acetone are condensed in the presence of dilute alkalis, water is eliminated according to Claisen (*Ber. Ber.* 14, 2470), and the methylketone of cinnamic acid is formed. When orthonitrobenzaldehyde is heated in the same way, there is, according to Baeyer and Drewsen (*Ber. Ber.* 15, 2856), no elimination of  $\text{H}_2\text{O}$ , but an aldole-like product—the methylketone of orthonitro  $\beta$ -phenyllactic acid—is formed, and this is only changed into orthonitrocinnamylmethylketone by the action of dehydrating substances. This difference in the behaviour of the substituted aldehyde has been explained by supposing that aldole-like bodies are formed in both cases, but that only the nitro compound possesses sufficient stability to enable it to exist under the experimental conditions imposed, whereas the non-nitrated body at once loses 1 mol.  $\text{H}_2\text{O}$ . Whether this stability might be owing to the mere presence of the  $\text{NO}_2$  group, or rather to its position in the molecule, was left an open question. The authors now answer this by studying the condensation of paranitrobenzaldehyde and acetone, and find that the nitro group in the para position acts exactly the same as if it were in the ortho position. *Paranitro- $\beta$ -Phenyllactic Acid Methylketone:* One part paranitrobenzaldehyde is dissolved in six to eight parts acetone, the solution is cooled with a freezing mixture, and a 1 per cent. solution of  $\text{NaHO}$  is slowly added with continual stirring until the liquid is slightly alkaline. Should any of the aldehyde separate by reason of the low temperature, the mixing vessel is removed from the freezing mixture till it redissolves. After neutralising the product with  $\text{HCl}$ , excess of acetone is distilled off, and the remaining oil and  $\text{NaCl}$  solution is poured on a large watch-glass. The oil congeals, and the pressed mass is crystallised from ether. The following equation shows the formation of the condensation product:—

It melts at 58° C., and dissolves readily in ether, alcohol, benzene, and glacial acetic acid, but is insoluble in ligroin and cold water. If boiled with acetic anhydride, acids, or even water, it is changed into paranitrocinnamylmethylketone (paranitrobenzylideneacetone), which melts at 110° C., and is identical with the product obtained by direct nitration of benzylideneacetone. Evidently, therefore, elimination of  $\text{H}_2\text{O}$  readily takes place in the para series:—

Mild oxidising agents, e.g., glacial acetic acid and  $\text{K}_2\text{Cr}_2\text{O}_7$ , change the condensation product into paranitrobenzoic acid, m.p. 237° C. Special interest is attached to the behaviour of the condensation product towards alkalis, since the latter change the ortho compound into indigo. *Paranitrocinnamylmethylketone:* To a dilute solution of the above-described lactic-acid-ketone in hot water, a 30 per cent. solution of  $\text{KHO}$  is added drop by drop, very slowly and with continual stirring, until a crystalline yellow precipitate is produced. If this is collected and crystallised from acetone it forms lustrous sulphur-yellow scales, little soluble in alcohol and acetone, not at all in ligroin and water, but readily soluble in glacial acetic acid. Its m.p. is 254° C. An analysis proves it to be paranitrocinnamylmethylketone. When oxidised by means of glacial acetic acid and  $\text{K}_2\text{Cr}_2\text{O}_7$ , it yields paranitrobenzoic acid, which shows that the nitro group has taken no part in the reaction. A participation, too, of the benzene nucleus is very improbable, because of its great stability in the nitrated condition, so that there only remains the supposition that the  $\text{H}_2\text{O}$  has been eliminated from a side chain, and accompanied by a condensation between the side chains. This explains the total difference of the substance from paranitrocinnamylketone and its great insolubility, but whether the condensation takes place between two or three molecules is not determined. The result, then, of the study of the action of alkalis on paranitro- $\beta$ -phenyllactic acid ketone is as follows: They effect the elimination of  $\text{H}_2\text{O}$  as well as a molecular condensation, whereas the action of acetic anhydride and of boiling water is simply that of water elimination. The products have no similarity with indigo, which is formed by the action of alkalis on the corresponding ortho compound, because the nitro group apparently remains intact when it is in the para position, whereas when in the ortho position its oxygen is transferred to the side chain, and acetic acid being eliminated, the atomic arrangement peculiar to indigo is brought about. The first stages of the reaction seem to be the same in both cases, however, and the above study shows that the initial move in the direction of the formation of indigo from nitro substitution products is the elimination of water from the side chain, whereby a complex atomic group is produced, which, in order to preserve equilibrium, depends not on the side chain of its own or of another molecule, but on the more promising ortho-nitro group.—J. J. H.

*Contribution to our Knowledge of the Colouring Matter obtained from Dimethylaniline and Chloranil.* H. Wichelhaus. *Ber. Ber.* 16, 2005.

THE author has at length succeeded in obtaining the colour base produced by the action of chloranil on dimethylaniline, in a pure state (*Ber. Ber.* 14, 1942). The base must be only incompletely precipitated from the salt solution in order to retain all excess of dimethylaniline in solution; it is then washed with water, dried, rubbed up with  $\text{NaHO}$  in order to remove traces of acid, washed, dried, and crystallised from ether. It forms small colourless prisms, insoluble in water, and little soluble in alcohol. Its melting point is 190° C. Its composition ( $\text{C}_{24}\text{H}_{20}\text{N}_2\text{O}$ ) is the same as that of the base of ordinary methyl-violet, but the properties of the latter are somewhat different. A fresh examination, therefore, of the base of methyl-violet seemed desirable, and the result has been to show that although its formula corresponds to the one just given, it is nevertheless a mixture containing about 27 per cent. of the above-mentioned crystalline base. A solution of methyl-violet, specially prepared from pure dimethylaniline, was precipitated with alkali, and the base thus obtained formed a reddish-brown readily-fusible powder, having the composition  $\text{C}_{24}\text{H}_{20}\text{N}_2\text{O}$ . It was repeatedly dissolved in dilute  $\text{H}_2\text{SO}_4$ , and as often precipitated with alkali without showing any change in appearance. It was then boiled with several quantities of ligroin, as long as anything dissolved, and in this way 30 grms. could be separated into 8 grms. of a crystalline body, and 22 grms. of a reddish-brown powder. Both products are very similar to each other, and dye wool and silk violet. The first

base may be crystallised from ether or from hot alcohol. Its melting point is  $190^{\circ}\text{C}.$ , and it possesses the same properties and the same crystalline form as the base obtained by means of chloranil. The second base, which amounts to over 70 per cent. of the base of methyl-violet, is a reddish-brown powder, insoluble in ether, and with melting point  $130^{\circ}\text{C}.$  When reduced by means of Sn and HCl, both bases yield different crystalline products. The first gives lustrous leaflets (melting point  $176^{\circ}$ ), which soon acquire a violet colour. They are identical with the reduction product of the chloranil derivative. The second base on reduction yields silver-gray prisms (melting point  $155^{\circ}$ ), which retain their gray tint for a lengthened period. It would appear, therefore, that the base derived from chloranil should have the formula  $\text{C}_{24}\text{H}_{30}\text{N}_3$ , and not  $\text{C}_{16}\text{H}_{20}\text{N}_2$  as was first proposed, and that it is probably an isomer of what forms the largest proportion of the base of methyl-violet.—J. J. H.

*On the Colouring Matter of Cochineal.* By H. Fürth. Berl. Ber. 16, 2169.

LIEBERMANN and Van Dorp (*Ann. Chem. Pharm.* 163, 97) obtained rubicoccin ( $\text{C}_{16}\text{H}_{10}\text{O}_6$ ) by the action of  $\text{H}_2\text{SO}_4$  on carmine, and by distilling rubicoccin with zinc powder they obtained a minute quantity of a hydrocarbon ( $\text{C}_{16}\text{H}_{12}$ ). The author obtained this same body by reducing in a similar way either coccinim (*Ann. Chem. Pharm.* 141, 329) or earmine itself, but in both cases the amount obtained was very small. When coccinim, mixed with many times its bulk of zinc powder, is heated in a tube, white vapours are first given off, which partly condense in the form of greenish-coloured leaflets; these were mixed with the yellow distillation product, also obtained in the condenser, and purified by repeated crystallising from ether, alcohol, and benzene, and finally by sublimation. The product (m.p.  $186^{\circ}$  to  $187^{\circ}$ ) is identical with that obtained from rubicoccin. If coccinim is heated with acetylchloride to  $100^{\circ}\text{C}.$  in a sealed tube, an acetyl compound of coccinim is produced, which separates from a hot alcoholic solution on cooling in the form of yellow crystals. It is insoluble in water, but readily soluble in alcohol and in glacial acetic acid. If the formula of the above-mentioned hydrocarbon is accepted as  $\text{C}_{16}\text{H}_{12}$ , the formula of coccinim is found to be  $\text{C}_{16}\text{H}_{14}\text{O}_6$ , and that of its acetyl derivative  $\text{C}_{16}\text{H}_{10}\text{O}_2 (\text{C}_2\text{H}_3\text{O}_2)_4$ . Coccinim would therefore appear to be the hydrate of a quinone of the hydrocarbon in question, and containing four hydroxyl groups. The hydrocarbon is also obtained from carmine, by simply heating the latter in a tube with zinc powder. The distillation product is dissolved in ether, the solution is shaken with KHO, then with HCl, and thus purified is allowed to crystallise. Its m.p. is  $186^{\circ}$ . It is identical with that obtained from rubicoccin by Liebermann and Van Dorp, and with that obtained from coccinim.—J. J. H.

*Action of Orthonitrobenzaldehyde on Aldehyde.* Ad. Baeyer and V. Driesen. Berl. Ber. 16, 2205.

IN a former paper (*Berl. Ber.* 15, 2856) the authors mention that by the action of a little  $\text{BaH}_2\text{O}_2$  water, on a solution of orthonitrobenzaldehyde in aldehyde, a crystalline body (m.p.  $120^{\circ}$ ) is produced. In order to prepare it, a 2 per cent. solution of NaHO is carefully added drop by drop, and with constant stirring, to an ice-cold solution of orthonitrobenzaldehyde in freshly-made aldehyde, until the alkaline reaction is persistent for at least five minutes. The liquid is then poured into a basin, excess of aldehyde is driven off by a current of air, and the crystalline product remaining is at once placed on an earthenware absorbent plate, and finally recrystallised from ether. It forms large colourless monoclinic prisms. It is readily soluble in alcohol, chloroform, etc. It melts at  $125^{\circ}\text{C}.$ , and gives off aldehyde vapour. An analysis gives numbers which correspond to a compound of orthonitrophenylactic-aldehyde with aldehyde ( $\text{C}_9\text{H}_7\text{NO}_4 + \text{C}_2\text{H}_4\text{O}$ ). Its aqueous solution gives off aldehyde even at a temperature of  $40^{\circ}$  to  $50^{\circ}\text{C}.$ , but on leading a current of air through such a solution it was not possible to obtain the free orthonitrophenylactic-

aldehyde in a crystallisable state. Both the free and the aldehyde compound, when acted upon by alkalis, give indigo. The free substance combines with a solution of a bisulphite, and reddens magenta sulphite. *Orthonitro- $\beta$ -Phenylactic Acid:* A solution of the condensation product in dilute alcohol is heated on a water bath with an excess of freshly-precipitated  $\text{Ag}_2\text{O}$  until a sample no longer yields indigo on the addition of alkali. The liquid is then boiled with HCl, filtered from  $\text{AgCl}$ , and extracted with ether. On evaporating the ethereal extract a crystalline mass possessing acid properties remains behind. It is purified by preparing its barium salt and decomposing this with HCl. Crystallised from water it forms short prisms (m.p.  $126^{\circ}\text{C}.$ ). It dissolves readily in water, alcohol, and ether, and is proved by analysis to be orthonitro- $\beta$ -phenylactic acid

When heated to  $190^{\circ}\text{C}.$  with dilute  $\text{H}_2\text{SO}_4$  it gives orthonitrocinnaunic acid. It is identical with an acid obtained recently by Einhorn from the addition product of HBr with orthonitrocinnaunic acid. When heated with concentrated  $\text{H}_2\text{SO}_4$  it gives a blue solution containing apparently indoin. *Orthonitrocinnaunic aldehyde:* This is produced by boiling the condensation product with acetic anhydride for about one hour until a sample on addition of NaHO no longer yields indigo. The excess of acetic anhydride is then driven off by evaporating, and the residual hot solution is decolourised with animal charcoal. The filtered liquid on cooling yields colourless needles which are recrystallised from ether. The pure substance melts at  $127^{\circ}\text{C}.$  It dissolves readily in boiling water and in chloroform, but only little in cold water, alcohol, and ether. Its formula is

It possesses all the properties of an aldehyde, forming a crystalline compound with sodium bisulphite, reducing an ammoniacal silver solution with formation of orthonitrocinnaunic acid, and when reduced itself yielding quinolin. The above shows, therefore, that the condensation of orthonitrobenzaldehyde with aldehyde takes place in the same sense as that with acetone when orthonitro- $\beta$ -phenylactic aldehyde

is formed, which, however, forms a still more unstable union with acetaldehyde.—J. J. H.

*New Coal-tar Colouring Matters.* Dingl. Polyt. Jour. 249, 383. (a) *New Yellow, Orange, and Brown Colouring Matters.* E. Nolting and E. v. Salis, Mayenfeld. Ger. Pat. 22268, 1882. (b) *Flavacilin.* E. Besthorn and O. Fischer. Dingl. Polyt. Jour. 249-385 (Comp. ibid. 247-48). (c) *Colouring Matters of the Saffranin Group.* R. Nietzki. Dingl. Polyt. Jour. 249, 386. (d) *Observations on the Saffranin Group.* R. Bindschedler.

(a) THESE are the  $\text{SO}_3\text{H}$  derivatives of nitrated secondary, and tertiary aromatic amines, or of tertiary amines containing two aromatic and one fatty radicle. They are obtained either by sulphonating the corresponding nitramines, or by the action of halogen-nitro compounds upon aromatic amidosulphonic acids. The following halogen-nitro compounds have been employed: Chlorodinitrobenzene, chlorotrinotrobenzene, or the chlorodinitrotoluene, parachlorodinitrotoluene, chlorodinitronaphthalene, chlorotrinotronaphthalene, chlorotetranitronaphthalene, in reaction with the following amines: aniline, ortho- and para-toluidine, the xylydines, methyl-ethyl aniline and homologues, diphenylamine, phenyltolylamine and ditolylamine, dinaphthylamine, amidoazobenzene, its homologues and substitution derivatives, etc. The resulting nitramines are converted by sulphonation into soluble bodies, which are the colouring matters in question, or such soluble bodies may be directly produced by using in place of the amine its  $\text{SO}_3\text{H}$  or  $\text{COOH}$  derivative. As an example, trinitrodiphenylaminesulphonic acid is described by the authors. It

may be directly obtained by heating together, in a flask attached to an upright condenser, 3 parts (1 molecule) sulphuric acid and 3 parts (1 molecule) picrylchloride with 2.5 parts sodium acetate in concentrated aqueous solution. The boiling is continued until the picrylchloride completely disappears; or the reaction may be more rapidly determined by heating under pressure at 120° to 150°. The following compounds are also mentioned as of special technical importance; the products of the action of picrylchloride, chlorodinitrobenzene, and chlorotetranitronaphthalene, upon amidazobenzene mono- and di-sulphonic acids, and phenylamidoazobenzene sulphonic acid. The reaction is of the same character as that above described. The proportions of the reagents are 35 parts amidoazobenzene disulphonic acid or of phenylamidoazobenzene sulphonic acid, 40 to 45 parts sodium acetate in concentrated aqueous solution, 20 parts chlorodinitrobenzene, or 25 parts picrylchloride or 35 parts chlorotetranitronaphthalene. (b) When flavolin ( $C_{16}H_{13}N$ ) is nitrated with fuming  $HNO_3$  it yields a nitro body, which on reduction is converted into flavaniline or monamidoflavin,  $C_{16}H_{12}NH_2N$ . Flavaniline is also formed by the action of acetyl chloride upon aniline sulphate at 100°, or upon acetanilid in presence of zinc chloride. It is evident, therefore, that valuable colouring matters are obtainable from complicated quinoline derivatives; and it is probable that such may be obtained from the high-boiling quinoline bases of coal tar, e.g., acridin. (c) Witt obtained (this Journal, 1882, p. 225) what he regarded as the first member of the saffranin series of colouring matters by the oxidation of a mixture of paraphenylenediamine (1 molecule) and aniline (2 molecules). The author has extended Witt's observations, using as his oxidising agent potassium bichromate in hot solution. He obtained similar compounds by using, in place of the aniline, ortho- or meta-toluidine, a mixture of either of these monamines (1 molecule) with paratoluidine (1 molecule), or a mixture of mono- or di-methylaniline (1 molecule) and any primary monamine (1 molecule), but not with secondary or tertiary bases, nor with paratoluidine alone. Similarly, in place of paraphenylenediamine, certain of its substituted derivatives may be used. Those, however, which contain an alcohol radicle in each  $NH_2$  group do not react. Diethylparaphenylenediamine oxidised in presence of aniline (2 molecules) yields diethylsaffranine, a magenta-red colouring matter. Its platinochloride, dried at 100°, has the composition

A mixture of paraphenylenediamine with aniline (1 molecule) and diethylaniline (2 molecules) yields on oxidation a body isomeric with the above. Both bodies yield green salts with sulphuric acid, but they neither form a green diazo-compound. *Tetrathylsaffranine* is formed from dimethylparaphenylenediamine, diethylaniline, and aniline. It differs from the preceding compounds in being much more violet in shade. It is observed in all cases that the formation of the saffranines is preceded by that of blue or green colouring matters, representing the intermediate stages of oxidation. With regard to the constitution of the saffranines it is now proved that they contain two amido-residues, united by an N-atom, which occupies the para-position in regard to the N-atoms of the amido groups, the simplest saffranine containing the group  $H_2N.C_6H_4.N.C_6H_4.NH_2$ . Its analogies with rosaniline are evident. When phenosaffranine is heated with concentrated HCl at 170° it yields a product which has the closest resemblance to aniline black. (d) If dimethylparaphenylenediamine (1 molecule) and diethylaniline (1 molecule) be treated with potassium dichromate in aqueous solution at 30° C., and in presence of zinc chloride, a separation of copper-coloured crystals,  $2C_{16}H_{19}N_3HCl.ZnCl_2$ , occurs in a few minutes. The new colouring matter, dimethylphenylene-green, is formed according to the equation—

It yields on reduction a corresponding leuco base. A corresponding ethyl derivative could not be obtained. If the above-mentioned zinc chloride compound be oxidised

in presence of aniline acetate it yields a beautiful violet colouring matter, which appears to be tetramethylphenylene saffranine, formed according to the equation—

Similar results are obtained by oxidising the dimethylphenylene-green in presence of para- and ortho-toluidin, xylinin, etc. Dimethylparaphenylenediamine and aniline (2 molecules) yield on oxidation dimethylphenylene saffranine ( $C_{26}H_{18}N_4$ ). Saffranines are decolourised on reduction. A solution of pure phenylene saffranine reduced in an atmosphere of hydrogen gas by means of a titrated solution of ferrous ammonium sulphate, was found in passing into the leuco compound to combine with 4H. The general formula for the saffranines is  $C_nH_{2n-22}N_4$ .—C. F. C.

*Process for Preparing Brown Azo-Colours from Chrysoidines and Diazo Compounds.* Actiengesellschaft für Anilinfabrikation, Berlin. Ger. Pat. 22714, Nov. 1, 1883.

THE chrysoidines (e.g., diamidoazobenzene hydrochloride) or their sulphonic or carbonic acids can combine with a second molecule of diazotised base or amido acid, forming colours of the type of phenylenediaminediazobenzene

The ordinary chrysoidine, e.g., yields with diazobenzene-chloride a brown colour. These colours can be converted into sulphonic acids, or the sulphonic acids of the components can be taken as the first materials from which to work.—J. G.

*Method for the Manufacture of Yellow Colouring Matters from Pyridine and Quinoline Bases.* Emil Jacobsen, Berlin. Ger. Pat. 23188, Nov. 4, 1882.

By heating phthalic anhydride with zinc chloride and pyridine or quinoline bases, to a temperature of 200° to 250°, yellow colouring matters are formed, which can be converted into soluble sulphonic acids. Similar dyes are obtained by using quinaldine in the place of pyridine or quinoline.—F. M.

*Method for the Preparation of a Blue Colouring Matter from Diethylaniline-azobenzene-para-sulphonic Acid.* Lembach and Schleicher, Biebrich-on-the-Rhine. Ger. Pat. 23278, Dec. 3, 1882.

To the ammoniacal solution of the sulphonic acid—

obtained from diethylaniline and para-diazo-benzene sulphonic acid, zinc-dust is added until the liquor is decolourised. The solution of the hydrazo-compound thus formed is acidulated and saturated with sulphuretted hydrogen. On adding ferric chloride a deep blue solution is produced, from which the colouring matter may be precipitated by common salt.—F. M.

*Method for the Preparation of Blue Colouring Matters.* Otto Mühlhäuser, Colour Works, Griesheim-on-the-Maine. Ger. Pat. 23291, Jan. 5, 1883.

LAUTH'S reaction (treatment with sulphuretted hydrogen, and subsequent oxidation) is applied to the sulphonic acids of the amidoazobenzene derivatives of substituted toluene and anisol. For instance, dimethyl-amido-methyl-azobenzene-sulphonic acid—

or dimethyl-amido-methoxy-azobenzene-sulphonic acid—

F. M.

*A New Blue Colour to be used as a Substitute for Indigo for Dyeing Cottons, Wool, and Silk.* William Heather Spence. A communication from Auguste François Chesnais, of Rouen. Eng. Pat. 1589, March 29, 1883.

THE inventor claims the use of a solution of an induline salt mixed with nitrosodimethylaniline blue (sulpho-conjugated) or methylaniline violet, etc., the application of

this mixed colour to the fabric, and its oxidation thereon by means of potassium dichromate. In order to prepare the solution the induline base is converted into its sulphate, acetate, or hydrochloride, and the salt dissolved in alcohol in the proportion of 120grms. to the litre. The methylaniline violet or nitrosodimethylaniline blue (sulpho-conjugated) is then added, and the liquid is said to be "fit for commerce." The dye is applied to the fabric by "tannate of tin," and then oxidised by passing through a chromate bath.—R. M.

*Improvements in Eol Dyestuffs suitable for Dyeing and Printing.* Sydney Pitt. A communication from the Verein Chemischen Fabriken, Mannheim, Eng. Pat. 2237, May 2, 1883.

THE new dyestuffs are azo compounds derived from alpha-naphthol instead of beta-naphthol. The sulphonic acids of alpha-naphthol are combined with the diazo derivatives of aniline, toluidine (ortho and para), xyldine, and other homologous bases, amidoazobenzene and its homologues, the naphthylamines, etc. Two methods are given for the manufacture of the sulphonic acids, the first consisting in the sulphonation of the naphthol by means of ordinary or fuming sulphuric acid at a low temperature, and the treatment of the mixed sodium salts thus obtained with boiling alcohol, which leaves the useless isomeride insoluble. In the second method (which is preferred) three modifications of alpha-naphthol sulphonic acid are claimed, these being derived from alpha-naphthylamine by the following processes: (1) Naphthylamine is mixed with the theoretical quantity of sulphuric acid and the mixture heated to 150° to 180° C. till soluble in alkali. (2) Naphthylamine is dissolved in from four to five times its weight of ordinary sulphuric acid, and heated to 100° to 120° C. till completely sulphonated. (3) Dry naphthylamine hydrochloride is stirred into cold fuming sulphuric acid containing 20 to 22 per cent. of free anhydride. These naphthylamine sulphonic acids are converted into the corresponding naphthol sulphonic acids by the usual diazo reaction, viz., by treatment with a nitrite and then boiling with water or dilute acid. The three sulphonic acids are stated to be isomeric, and all applicable for the production of red dyes by combination with the diazo compounds specified.—R. M.

*Improvements in the Manufacture of Dyes.* Gustav Adolph Bang. A communication from Gustav Adolph Dahl, Ernst Dahl, and Rudolph Dahl, Dahl and Co., Barmen. Eng. Pat. 2296, May 5, 1883.

THIS invention claims the production of azo dyes by the action of diazobenzene and its homologues, diazoanisole, diazonaphthalene, and diazo-azo compounds upon what is described as the "monosulphate of alpha-naphthalene derived from naphthalene" (alpha-naphthol-monosulphonic acid?). The dyes are said to be yellow-red, scarlet, and blue-red.—R. M.

*Improvements in Converting Anthraquinone into a Monosulpho Acid of Anthraquinone, also applicable for treating other organic compounds.* Ivan Levinstein. Eng. Pat. 2299, May 7, 1883. Provisional protection only.

THE improvement consists in heating the quinone with fuming sulphuric acid in a closed enamel pan provided with an agitator having a hollow shaft, through which the contents are discharged by air pressure when the operation is complete.—R. M.

*Improvements in the Manufacture of Alpha- and Beta-Naphthol.* Ivan Levinstein. Eng. Pat. 2300, May 7, 1883.

IN making the naphthols by the usual method of fusing the sodium salts of the naphthalene-sulphonic acids with caustic alkali, the inventor allows the melt to separate into two layers, the upper of which consists of sodium naphtholate and the lower of sodium sulphite, hydroxide, and impurities. The lower layer is utilised for the preparation of the sodium salts of the naphthalene-sulphonic acids. The sodium naphtholate which forms the upper layer is removed and decomposed by acid in the usual way.—R. M.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

*Method and Apparatus for Treating (Washing, Dyeing, etc.) Textile Fibres, Yarn, and all kinds of Cloth.* Otto Obermaier, Lambrecht, Pfalz. Ger. Pat. 23117. Dec. 6, 1882.

THE apparatus consists of a vessel with a charging space M, in which the textile stuff is compressed, and held compressed by a screw piston. This vessel is composed of two concentric cylinders BC, with perforated sides and closed bottoms, the inner cylinder being set upon a pipe which is connected to a pump. The vessel stands in an outer vessel A, provided with a heating arrangement R, and connected by a valve with the pump G,

and it is so arranged that the liquid, which is forced at a high pressure by the pump G into the perforated cylinder C, penetrates the textile stuff M, and passes through the perforations from B to A, where it is warmed again, and then passes through the valve K back into the pump, in order to begin the round again. The vessel for holding the textile stuff can be made to rotate. For filtering purposes, and in order to keep back pieces of fibre, and to prevent the textile stuff from coming into contact with the metal surfaces of the apparatus, a filter is placed in the smaller cylinder, and the perforated sides of the charging space are covered with cloth. Several of these apparatus may be united to form a battery, in which case the single basins A are arranged together and connected with one another.—W. M.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Bistres for Dyeing and Printing.* Dingl. Polyt. Journ. 249, 35, 1883. From the Moniteur Scientifique, September, 1882.

ACCORDING to Naquet, a good solution for producing a bistre on cotton fabrics is composed as follows: Bismuth, 100 parts; nitric acid, 280 parts; tartaric acid, 75 parts; ammonia, 0.06 part; sodium thiosulphate, 75 parts; water, 2,000 parts. Fabrics saturated with this solution, when dried at 25° to 30°, gradually develop a clear chestnut brown, whose intensity reaches a maximum after 24 hours. By steaming the dried saturated fabrics there is produced a darker chocolate catechu, which is much intensified by treatment with a weak solution of sodium thiosulphate. In this case, owing to the complete conversion of all the bismuth into sulphide, the fabric possesses a dull yellowish tint and unpleasant metallic lustre. The above solution does not deteriorate on keeping, even in contact with the atmosphere. Upon the constitution and production of manganese-bistre, recent experiments by Balanche throw some light. It is found that no reaction takes place between manganous

chloride and potassium bichromate, but that if the latter be substituted by the monochromate an abundant bistre-coloured precipitate falls. By printing, therefore, with the following mixture—180grms. potassium dichromate, 850grms. water, 150grms. wheat-starch paste, 210grms. manganous chloride, 210grms. sodium acetate liquor of 16·5 B., and steaming, a dark well-fixed bistre is developed which withstands washing and soaping, and does not injure the fabric. The formation of this colour is here due to the decomposition of the sodium acetate, and consequent conversion of the potassium bichromate into the monochromate. The constitution of this bistre is possibly  $\text{MnCrO}_4 \cdot \text{MnO}_2 \cdot 11\text{H}_2\text{O}$ , and is at present the subject of further investigation.—W. D. B.

*An Improved Process of Turkey-Red Dyeing for Cotton Yarns and Cloth.* John William Hoffmann. A communication from Carl Seeber, Schopfheim. Eng. Pat. 2289, May 5, 1883. Provisional protection only. THE yarn is first treated with a boiling solution of soda ash and resin, then with an oil mordant composed of Turkey-red oil, "stannate of soda," and ammonia liquor. An alumina mordant is then applied, and finally a chalk bath. The inventor claims a saving of time and economy of cost.—R. M.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Preparation of Ammonium Sulphocyanide.* J. Schulze. Journ. f. Prakt. Chem. 27, 578.

THE author recommends for this purpose the action of ammonia upon carbon disulphide in alcoholic solution, as already proposed by Millon. From 600grms. alcohol (95 per cent.), 800grms. ammonia solution (sp. gr. 0·912), and 350grms. carbon disulphide, the author obtained 280grms. of dry ammonium sulphocyanide.—C. F. C.

*On Aluminium Sulphocyanide free from Iron.* Dr. Gottlieb Stein. Dingl. Polyt. Journ. 250, 36.

SINCE the introduction by Stork and Strobel (*Dingl.* 241, 464) of aluminium sulphocyanide, in the place of aluminium acetate for making alizarin steam-reds, the author states that it has become a point of importance in buying aluminium sulphocyanide to obtain it as free from iron as possible, since preparations containing iron produce duller and bluer reds than those which have been purified from iron. All commercial samples of aluminium sulphocyanide show the presence of iron when tested with yellow prussiate of potash, and it is present in largest quantity when ammonium sulphocyanide obtained from gas-liquor has been used to produce the aluminium compound. The iron exists in the preparation chiefly in the form of ferric sulphocyanide,  $\text{Fe}_2(\text{CNS})_6$ , and since this compound dissolves in ether, as is well known, forming a red solution, while the aluminium compound, on the other hand, is not very soluble, the author has tried the process of extraction by ether on the scale of a laboratory experiment, and finds that by treating 1 kilog. of aluminium sulphocyanide, of sp. gr. 21° B. (containing 25 per cent. sulphocyanide), with three successive portions of 660grms. each of ether, he obtains a preparation of aluminium sulphocyanide which shows but a faint trace of iron when tested with potassium ferrocyanide. The ether which mixes to some extent with the aluminium sulphocyanide reduces the specific gravity of the solution after the third extraction to 12° B., and to prevent the separation of sulphur which takes place if the ether is left in the solution it must be rapidly distilled or evaporated off. This process of extraction can be used also as an analytical method for determining the quantity of iron in a sample of aluminium sulphocyanide, by evaporating the ether solution to dryness, and estimating the iron in the residue by any of the well-known methods.—H. S. P.

*Improvements in Concentrating Sulphuric Acid, and in Apparatus therefor.* W. P. Thompson, Liverpool. Communicated by W. West, Denver, U.S.A. Eng. Pat. 1651, 1883.

SULPHURIC acid of from 48° to 50° B. is evaporated in

a lead pan up to 60° B. It is then fed into a cast-iron retort interiorly "lined or enamelled with porcelain or other vitreous substance." In this it is evaporated to a density of 66° B. Arrangements are described by which the operation can be conducted continuously.

*Improvements in the Mode of Concentrating Sulphuric Acid and in Apparatus for the same.* S. Bowen Bowen, Llanelly. Eng. Pat. 2035, 1883.

THE author of this invention uses "a series of retorts made of glass or any other suitable material, with inlet and outlet passages in the sides or ends of each retort sufficiently large to allow the volume of weak vapour to pass from the lowest retort through the series, and also serving to conduct the acids from the highest to the lowest retort, by means of glass tubes or adapters connected to each retort, the weak vapour ultimately passing through a small condenser to the chimney. By the vapour passing through the series, the more dense vapour of the lower retorts becomes condensed as it passes through the space of the adjoining retorts, so that when it leaves the last retort it is in a very weak state." The retorts should be arranged at successive elevations, "so as to allow the acid to run from the highest retort to the lowest. . . . The retorts are placed in chamber spaces, heated by fires underneath. Hot acid of specific gravity 1·750" is fed into the topmost retort of the series, and concentrated acid flows off from the lowest one. An arrangement is described for automatically regulating the supply of acid to the topmost retort.

*Improvements in the Manufacture of Oxide of Strontium and Hyposulphite of the Alkali.* W. Moody, West Ham. Eng. Pat. 2259, 1883.

HAVING obtained strontium sulphide by deoxidising strontium sulphate by furnacing it in admixture with coal, the author of this invention mixes the said sulphide, while still hot, with water, "to form a thin pasty mass." He then boils this mass with a quantity of caustic alkali "sufficient to combine with the sulphur of the sulphide." On cooling, strontium hydrate crystallises out. The mother-liquor consists of a solution of sulphide of sodium or of potassium, according to the alkali which has been employed. This may either be simply concentrated by evaporation until hydrated sulphide will crystallise from it on cooling, or it may be treated by sulphurous acid, for the conversion of its sulphide into hyposulphite with precipitation of free sulphur.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*Improvements in the Manufacture of Sulphate of Lime or Plaster-of-Paris.* J. H. Johnson, London. Communicated by P. G. Jourmet, Paris. Eng. Pat. 2566, 1883.

THE author of this invention makes slaked lime into a paste with dilute sulphuric acid, partially dries that paste, and then calcines it, thus obtaining either "anhydrous plaster or a mixture of anhydrous plaster and lime," according to the proportion of sulphuric acid which has been used. By varying the proportions of sulphuric acid employed he obtains "a large variety of products of similar nature, but differing in degree of hardness and in the time they require for setting."

*Improvements in the Manufacture of Artificial Stone and Cement.* E. S. Shepherd, Puddington, and J. L. Aspinwall, Nantlle Vale, Carnarvon. Eng. Pat. 2352, 1883.

THE author of this invention proposes to employ in the manufacture of artificial stone and cement the debris of slate quarries.

*A New or Improved Combination of Materials for making Cements, capable also of being used for other useful and ornamental purposes.* T. Smith, Sunbury. Eng. Pat. 2199, 1883.

THE scrapings of macadamised roads are washed to remove from them "all light or superfluous matters," and are then "thoroughly baked," and afterwards finely ground. The product is then mixed with dry powdered chalk and coke-dust, in the proportions of 43 parts of the said product to 20 parts of chalk and 37 parts of coke-dust, and the mixture so obtained is then incorporated with molten sulphur. Sand may be used instead of the road scrapings, and for some applications of the composition, as for jointing pipes, pitch or bitumen may be substituted for a part of the sulphur.

*Improvements in the Manufacture of Artificial Stone for various Purposes and Material applicable as a Substitute for Emery.* B. Hess, Bayreuth. Eng. Pat. 2321, 1883.

THE materials to be used under this invention are "serpentine (or kindred minerals), feldspar, mica, quartz, and fireclay, or some of these variously combined, according to the purpose for which the artificial stone is intended." They are finely ground, mixed in the desired proportions, "moistened with so much water that the mass will remain conglomerated if compressed by hand," and the moist mixture is then compressed in moulds, so that when removed from the moulds it will retain the form given to it by them. "The so-formed stones, plates, vessels, or other objects, are afterwards well but slowly dried under the influence of a gradually increasing temperature, and are finally burned in a strong white heat."

## X.—METALLURGY, MINING, Etc.

*On the Modern Methods of Manufacturing Iron and Steel, on the Methods of testing these Materials, and their Characteristic Properties.* Franz Kupelwieser. Dingl. Polyt. Journ. 250, 37, reprinted from the "Wochenchrift des Oesterreichischen Ingenieur- und Architektenvereins," 1883, 187-191.

THIS paper deals with the difficulties which manufacturers of iron and steel, especially steel rail makers, have to contend with to satisfy the conditions specified by consumers with regard to the quality, dimensions, etc., of the articles manufactured. The various methods for making malleable iron and steel from pig iron are first briefly described, dividing the processes roughly into two classes, those in which the temperature is not so high that the metal is in the fluid state at the end of the operation, as in the ordinary puddling furnace and the charcoal hearth finery, and those in which the purified iron is in a fluid state at the end of the process, as in the crucible steel process, the Bessemer process and the Siemens-Martin process. One of the chief advantages of the latter class is that the slag and cinder are more completely separated from the metal. It is also a fact that melted steel absorbs large quantities of gases, which have been found to be principally hydrogen and nitrogen. These occluded gases have the tendency to form bubbles in the ingots, and must of course tend to prevent the metal being, in subsequent treatment, rolled or welded to absolute uniformity of physical structure. The Siemens-Martin process in this respect has an advantage over the Bessemer process, in that less gas is likely to be occluded by steel made by the Siemens-Martin method than by the Bessemer method. As regards the chemical influence of these occluded gases, the question has not yet been satisfactorily decided. The author then discusses the causes affecting the characteristic qualities of the manufactured steel, and classifies them as follows: (1) Chemical composition, (2) homogeneity of the ingot steel, and (3) the mechanical treatment. He then describes briefly the effect that the various elements found together with iron in steel have upon the physical properties of steel, and quotes the experiments of Stubbs and Snelus, showing that these elements are unequally distributed in an ingot of cast steel. He then speaks at some length of

the influence of mechanical treatment. By this the quality can be either improved or deteriorated. By working the material down from a piece of large cross section to a piece of small cross section, the tendency of the operation is to improve the quality. It is a known fact that by a sufficiently prolonged mechanical treatment steel can be made to bear a greater tensile strain. The process of reducing the area of the cross section of a piece of steel tends to make the material denser, to squeeze the sides of bubbles in the ingot closer together, and, when a proper temperature is maintained, to weld the walls of such bubbles together, to make the texture of the metal finer grained, and, assuming that the mechanical treatment is continued during a gradual fall of temperature in the metal, to make the breaking strain greater. If, on the other hand, the section at the beginning of the operation is not one suitable to the machine employed, the choice of a too large section may become as great an error as the choice of too small a section, as, in order to obtain the final section required, the metal has to be worked towards the end of the operation at too low a temperature. The reason why rails from Austrian works are weaker than those made in German, in spite of the unrolled steel being at least as good if not better in Austrian works than it is in German, is that in Germany there is a more perfect arrangement in the works, enabling a greater reduction of sectional area by mechanical treatment to be effected. The unequal distribution of the metal in the section of the finished product has also a great influence upon the resulting quality of the manufactured article. Those portions where there is most metal remain the hottest, whilst the thinner portions get more rapidly cool, and are thus worked at a lower temperature, and become therefore harder and also more brittle. The harder the material is to begin with the worse this feature becomes. In rail-making, for instance, the head of the rail contains more metal than the foot, and hence the foot at the end of the rolling is colder than the head, and is therefore harder, whereas it would be more desirable to have the softer metal in the foot rather than in the head. The effect of unequal cooling can be seen by the eye in almost every broken rail-section. Sometimes a rail breaks without any apparent reason. Often the cause is to be found, not in any imperfection of material or manufacture, but in the fact that the section of the rail was designed without any consideration being given to the peculiar properties of the metal of which it was to be made, and simply because that section gave the greatest calculated carrying power for the smallest quantity of material. The author lays stress upon the point that it is not possible in the manufacture of an article on a large scale to obtain a product perfect from all theoretical points of view, since it is impossible to heat the material to exactly the same temperature in all its parts, and in removing it from the furnace, and during its mechanical treatment, heat is unequally lost, so that the mechanical treatment cannot be conducted under equal conditions of temperature, and hence the same article shows different properties when tests are applied to different parts of it. Beyond this, it must be borne in mind that the machines used are not instruments of precision, since they require the expenditure sometimes of thousands of horse-powers, and since they have to deal with iron at a high temperature. All idea of working with precision ends when one has to deal with hot metal, since with every change of temperature in the metal being rolled, changes in the size of the rolls take place, and with these, changes in the measurements of the manufactured article. Of course, more perfect machinery makes a more perfect article; but it is sometimes striking that the requirements of consumers go so far as to be beyond attainment, even with the best materials and the most careful work, and that among the requirements are some which depend upon or demand properties totally inconsistent with those necessary to satisfy others. The author then instances some cases in which measurements are demanded for rails which cannot possibly be uniformly attained, and with regard to which little toleration is allowed; other cases in which a certain chemical constitution is required, the rails being rejected unless this be satisfied, although they may for all practical purposes be excellent

in quality and satisfy all breaking or tensile tests. He concludes by remarking that by the requirements of the consumers, by the difficult conditions of contract, by the number of different sections demanded by different consumers, necessitating a corresponding number of sets of rolls, and by the inconveniences of the contract itself, the cost of manufacture is increased, and therefore also the selling price, which can hardly be a matter of small importance to the purchaser.—H. S. P.

*Improvements in the Method of and Apparatus for Depolarising Electric Baths in the Refining and Deposition of Metals.* A. M. Clark, London. Communicated by C. de Changy, Levallois-Perret, France. Eng. Pat. 2281, 1883.

THIS invention consists in a method of "automatically depolarising electrolytic baths, which method consists in breaking, diminishing, or increasing the contact of the main current, and making, approaching, or receding from a contact with the circuit of the electrolytic bath or baths with or without breaking the main circuit."

*Improvements in the Manufacture of Nickel and of Cobalt, and of Alloys of either of these Metals with Iron.* A. M. Clark, London. Communicated by the Société Anonyme Fonderie de Nickel et Métaux Blancs, Paris. Eng. Pat. 2243, 1883.

THIS invention consists in melting together, "in the same crucible, metallic nickel or cobalt with cyanide or ferrocyanide of potassium (with the addition of iron when desiring to produce ferro-nickel and ferro-cobalt) in presence of an oxide of manganese." "By treating nickel, cobalt, ferro-nickel, and ferro-cobalt with oxide of manganese and cyanide or ferro-cyanide of potassium, with or without the addition of a very small proportion of aluminium, I not only obtain metals and alloys suitable for rolling and drawing, but I am enabled to obtain castings of these metals and alloys (which has never hitherto been practically possible) suitable for the manufacture of surgical instruments, cocks and valves, locksmiths', carriage smiths', and gunsmiths' work, etc."

*A New or Improved Process for Manufacturing Metallic Oxides or Bases.* H. A. Bonneville, Paris. Communicated by L. C. E. Faucheux, Loos, France. Eng. Pat. 2055, 1883.

THIS patent claims the "principle" of decomposing the metallic sulphides by steam, superheated or not.

*Improved Processes for Obtaining Aluminium from its Ore or from other Substances.* H. A. Gadsden, London. Communicated by E. Foote, New York. Eng. Pat. 1995, 1883.

THE author of this invention proposes to treat either double chloride of aluminium and sodium or double fluoride of aluminium and sodium by vapour of sodium, evolved from retorts in which a mixture of carbonate of soda with carbonaceous matter is intensely heated.

*Improvements in the Use of Slags or Scoria Obtained as Waste Products from the Manufacture of Steel by the Converter Process, etc.* J. Wright, London. Eng. Pat. 1657, 1883.

THE object of this invention is to recover from converter slags the "small masses of steel and iron, in different metallic states and in volumes varying from a very small shot up to the size of a walnut," which the inventor states to sometimes constitute 20 per cent. of the weight of such slags. He crushes the slags, in such wise that the other constituents thereof are reduced to powder while the said small masses of metal "resist disintegration and retain their volume," and he then separates the latter "by means of sieves of various meshes."

*Improvements in the Method of and Apparatus for Manufacturing Metallic Alloys, more particularly those of Zinc.* G. Selve, Altena, Germany. Eng. Pat. 2995, 1883.

IN order to diminish loss of zinc by volatilisation in the manufacture of brass, and to prevent the workmen employed in that manufacture having to be exposed "to a high degree of heat and the injurious fumes of zinc," the author of this invention proposes to employ in that manufacture specially deep crucibles, fitting into apertures in the arch or roof of a regenerative furnace in suchwise that only the lower part of each crucible descends into the furnace and is heated thereby, the upper part of the crucible extending above the roof of the furnace, and so being exposed to the atmosphere. "Copper is first placed in the crucible, and is melted at a temperature of from 1,922° to 2,192° Fahr., and the zinc is then quickly added, . . . so much brass waste being then added as to render the whole pasty, while at the same time cooler layers of metal are by this means formed in the upper part of the crucible. As, in addition to this, the upper part of the crucible is outside the furnace, the upper layers of metal are of a much lower temperature than those below, and they are maintained at this low temperature by successive further additions of cold brass waste, thereby causing the condensation of the greater part of the zinc vapours as they rise up into the cooled layers from the lower highly-heated layers of metal. After the whole of the metal is melted, the crucible is removed and the contents stirred, so as to obtain a homogeneous alloy." The inventor states that the loss of zinc incurred in the manufacture of brass by this method is from 50 to 75 per cent. less than the loss of zinc in the ordinary method of manufacturing that alloy.

*Improvements in the Utilisation of Phosphatic Metallic Scoria.* G. Pitt, Sutton. Communicated by G. Roecour, Liège, Belgium. Eng. Pat. 1743, 1883.

BY this invention the slags produced in the basic process of manufacturing steel are to be fused in a cupola or blast furnace in a reducing atmosphere. The slags "should contain or be mixed with such fluxes as to contain as a whole about 3 to 4 parts of iron and manganese together for 1 part of phosphorus, and 30 to 50 of silica for 50 to 70 parts of alumina, lime, and magnesia together. The fuel should be coke, anthracite, or charcoal, and the temperature high enough to reduce a large portion of the manganese oxide" contained in the slags operated upon. The products are said to be "a phosphoric matte, with 20 to 25 per cent. of phosphorus, and a slag very poor in phosphoric acid." Two methods of dealing with the phosphoric matte are described. (1) The matte "is blown in a basic converter as ordinary pig iron, with the addition of 2 to 4 parts of lime or calcined dolomite for 1 part of phosphorus in the matte. . . . On leaving the converter before complete de-phosphorisation of the metal, a slag very rich in phosphoric acid and rather poor in manganese and iron can be run, which slag can be treated by sulphuric acid for superphosphate for agricultural purposes." The metal remaining in the converter can then be completely de-phosphorised in the usual way. (2) The phosphoric matte "is ground and mixed with 3 to 7 parts of sulphate of soda or potash for 1 part of phosphorus in the matte, and about one half part of coal or coke." The mixture so obtained is then heated in a reverberatory furnace, first in a deoxidising atmosphere, and then, after a certain time, "under an oxidising flame, and the temperature raised as high as possible." The products are phosphate of soda or potash and sulphides of iron and manganese. The former is then separated from the latter by lixiviation.

*Treating Blast-Furnace Slag to obtain therefrom certain Products useful for various purposes.* E. G. Colton, London. Communicated by A. D. Elbers, Hoboken, U.S.A. Eng. Pat. 2252, 1883.

BLAST-furnace slag is first to be converted into "slag-fibres, known as slag-wool, mineral wool, and silicate cotton," and the said slag-fibres are then to be "heated

and fritted" until "they are reduced to white friable silicates, which are then pulverised." The product so obtained is said to be suitable for use (1) "As a flux or glaze for china, pottery, and enamelled ware, or as the body or main constituent in making new kinds of pottery and similar ware. (2) The manufacture of glass. (3) In making ornamental plastering, stucco, statuary, and artificial stone, mixed with lime, in the same manner as these products are now made from fine cements. And (4) as a paint or body for pigments."

*Preparation of Basic Bricks from Strontianite.* G. Stöckman, Ruhrort. Ger. Pat. 24226, Sept. 21, 1882.

THE raw or burnt strontianite is mixed with clay or argillaceous ironstone in such proportions that the bricks shall contain about 10 per cent. of silica, and then it is worked into a plastic mass with tar or heavy hydrocarbons, and pressed into bricks. After coming out of the moulds the bricks are dusted with fine clay or ironstone, dried, and burned. The effect of dusting is that during the burning the clay combines with the strontia and forms a glaze which protects the bricks from the moisture in the air.—W. M.

*Water Cooling for Bessemer Hearths.* Willy Schmaechtenberg, Hoerde. Ger. Pat. 23309, Aug. 16, 1882.

THE water passes through an annular space in the converter-trunnion, as shown, to a canal *d* in the con-

verter-ring; from thence, by tubes *c f*, to water spaces *i* in the tuyere plate. From here the water returns by the tubes *k k* to a central pipe in the trunnion, and thence, as shown by elbow-pipe *m*, to the waste pipe *n*.—J. T.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*Refining, Deodorising, and Purifying Oils and Fats, etc.* A. C. Tiehenor, Alameda, U.S.A. Eng. Pat. 2229, 1883.

THE various objects of this invention are to be accomplished by passing electric currents through the bodies to be refined, deodorised, and purified.

*An Improved Process for the Manufacture of Vegetable Oils.* C. F. Stollmeyer, London. Eng. Pat. 2334, 1883.

THIS invention consists in "breaking or bursting the oil cells" of seeds by heating them in closed vessels with water under a pressure of 75 lb. to the square inch. The resulting mixture of water, oil, and pulp which is then discharged from the said vessel is allowed to stand till all the oil has collected at the top. The supernatant oil is then drawn off, and the pulp is then submitted to pressure for the extraction of the oil still remaining in it. The inventor claims that this process gives "a greater yield of oil and a purer and better article" than can be obtained by the processes at present in use.

*Apparatus for Extracting Fat under pressure from Bones and other Materials.* Werner Schneider, Lehrberg, near Aunsbach. Ger. Pat. 22295, May, 1882.

THE bones having been filled in, some petroleum spirit is introduced through the pipe *m* and raised to boiling by means of steam which passes through the worm *d*. The vapours pass through *e* into the condenser. When

the bones are sufficiently heated and the air is expelled from them, cold petroleum spirit is injected under strong pressure through the pipes *o* and *p*, and the roses *ff*<sup>1</sup>. The spirit in *A* is then heated again. Part of it is thus evaporated, and is then forced back under pressure through the roses. These operations are repeated several times. The claims of the patentee refer to the use of the perforated pipes *f*<sup>1</sup>, which are placed at the sides of the apparatus, and below the surface of the layer of bones, in order to force the solvent also from the side into the materials which are to be extracted.—J. G.

*A Process of Decomposing and Transforming Fats or Fatty Substances into Fatty Acids and Glycerine.* A. Marix, Paris. Eng. Pat. 2349, 1883.

By this invention fatty substances are digested with water and "a neutral substance acting purely as a mechanical agent for opening up the molecules and breaking through the albuminous film surrounding the same." The said neutral substance may be "carbonate of magnesia, talc, pipeclay, chalk," etc. The proposed mode of procedure, and special apparatus for it, are described in detail.

*New or Improved Process for Purifying Glycerine.* H. J. Haddan, London. Communicated by C. Moldenhauer and Dr. C. Heinzerling, Frankfurt-on-Main. Eng. Pat. 2326, 1883.

GLYCERINE from soap-makers' leys is usually contaminated by common salt, and thereby rendered unfit for some of the purposes to which glycerine is applied in the arts. The main object of this invention is to purify glycerine from salt. The crude glycerine is first "completely separated from water," and is then "mixed with once or twice its volume of pure methyl or ethyl alcohol, and, if this mixture be not alkaline, from 1 to 10 per cent. of carbonate of soda is added." Certain salts precipitate, and are then separated by filtration. Sulphuric acid is then added to the mother-liquor until it has an acid reaction. The sulphuric acid decomposes the various sodium salts of organic acids present in the mother-liquor, and the resulting sodium sulphate separates out, and is removed by a second filtration. The filtrate "is now mixed with lead oxide or soluble lead salts or other metallic salts which form insoluble compounds with chlorine, in sufficient quantities to precipitate the latter." The resulting precipitate having been removed by a further filtration, the final filtrate is distilled, to drive off its alcohol. "At the end of this operation, vapours of ether pass over, which have been produced from the volatile

organic acids, such as propionic and butyric acids, contained in the ley, in the presence of alcohol and acid. The treatment with alcohol, therefore, serves to remove, not only the common salt, but also, in the shape of volatile mixed ethers, the volatile fatty acids contained in the crude glycerine, which acids are very prejudicial, especially in the manufacture of nitro-glycerine."

*An Improvement in the Treatment of Fats for the Manufacture of Soap.* J. Murray, London. Communicated by J. A. F. Bang and J. de Castro, Paris. Eng. Pat. 3658, 1883.

"FATS are frequently subjected to the action of heated water with a little zinc powder in a close vessel, for separation of the glycerine before saponification. The fatty acids act on the metal of the vessel, producing compounds which, mingled with the fat, seriously discolour the soap produced from it. This invention relates to means of preventing this discolouration. For this purpose, the fatty matter, after being treated in the usual way for separation of the glycerine, is poured into a vessel lined with lead, and while still hot it is treated with sulphurous acid applied either in solution with water, or blown through the material to which water is added. The sulphurous acid acts on the metallic compounds, forming new compounds which are soluble in water, and can be drained off with the water, and it also to a certain extent bleaches the fatty matter, especially that which is of vegetable origin, so that the soap produced from it is free from objectionable discolouration."

## XII.—PAINTS, VARNISHES, AND RESINS.

*Improvements in the Process and Apparatus for the Preparation of Clear Amber Varnish.* Bernhard Borowsky, Stargard, Pomerania. Ger. Pat. 21909, July, 1882.

THE molten amber, which has been mixed with oil, is diluted with a considerable quantity of turpentine, and put away for several weeks, when all impurities will settle out. The clear solution is siphoned off, and placed

in a distilling apparatus, in which the excess of the solvent is distilled off by means of air, which is blown through. The remaining mass has the consistency of syrup, and is diluted with turpentine before being used. The apparatus contains perforated rimmed plates *g*, the air passing through slits which are in the latter. The apparatus is heated by means of the steam casing *f* and the pipe *i*. The oil enters through pipes *n* and runs off at *h*. The air enters at *h*, and leaves at the top, carrying away the vapours.—J. G.

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

*An Improved Process for Removing the Hair or Wool from the Skins or Hides of Animals, and also for Cleansing, Softening, Swelling, and Preparing the same for subsequent Treatment in the Production of Leather.*

THIS invention "consists in subjecting hides or skins alternately to the action of water and to that of the open air."

## XIV.—AGRICULTURE, MANURES, Etc.

*Process for Destroying the Vine Louse and other Injurious Insects by the Application of Pyridine Bases.* Julius Rütgers, Vienna. Ger. Pat. 24295, Nov. 30, 1882.

THE pyridine bases are obtained from the portion of coal-tar oil boiling between 80° and 250° C. by agitating it with a mineral acid and then treating the acid extract with soda ley and distilling with steam. The bases or their aqueous solution are syringed either on to the vines or on the soil, or are blown in the form of vapour in the freshly turned up earth. When salts of the pyridine bases are used, decomposition generally takes place by the action of the alkaline earth carbonates in the soil, the bases being liberated, or this decomposition is effected by spreading lime or carbonates on the ground. This mixture of bases acts very energetically and lasts long, owing to the vapour being retained in the ground.—W. M.

*Improvements in the Manufacture of Fertilisers.* H. J. Allison, London. Communicated by the Scribner Process Company, New York. Eng. Pat. 4036, 1883.

THE authors of this invention calcine ferruginous and aluminous phosphates, "bringing into contact with the phosphates, while hot, either the vapour of sulphur or sulphurous anhydride." They state that the product is "a commercially valuable fertilising compound, containing a large percentage of available phosphoric acid," and that it may "without further treatment be mixed with potash salts, or ammoniacal matters," valuable manures being thus produced without the use of sulphuric acids.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*Method and Apparatus for Converting Ordinary Alcohol Distilling and Rectifying Apparatus into continuous ones.* J. A. Stelzner, Alchemnitz, near Chemnitz, Saxony. Ger. Pat. 22464, March 26, 1882.

THIS method has for its object the production of pure spirit by one distillation. The crude spirit, which has previously been mixed with certain materials serving for

its purification (oil, acids, alkalis, alkaline carbonates, etc.), is introduced into the still by means of the spray apparatus *K*, which is kept in continual action by an injector. Here it mixes with steam, escaping from the

spreading pipes  $J_1$  and  $J_2$ , whereupon the mixed vapours ascend into the rectifying column. In this manner a uniform low temperature is maintained, and therefore no heavy vapours are carried over. The latter accumulate in the lowest partition of the rectifying column, from which they are carried off through the pipe  $p$  into another small column, in which they are farther separated.—F. M.

*An Improved Process of Purifying Water and adapting it for Brewing and other purposes, and Apparatus therefor.* E. M. Dixon, Glasgow. Eng. Pat. 2112, 1883.

Two methods of purifying water are described in the specification of this invention. One "consists in adding slaked lime to the water and injecting air, then separating the sediment, and subsequently injecting carbonic acid into the water;" the other in "first dissolving in the water slaked lime and injecting air while a high temperature is maintained, then adding hydrochloric acid or sulphuric acid or other suitable reagent, and subsequently injecting carbonic acid, and filtering or decanting."

### XIX.—PAPER, PASTEBOARD, Etc.

*An Improved Process for Sizing Paper and Textile Fabrics, which is also applicable to the manufacture of Parchment Paper, Leather Boards, etc.* C. Weygaug, Childs Hill. Eng. Pat. 2251, 1883.

THE sizes to be used under this invention are starch and animal glue. With them are to be used various "astringent metallic salts," as sulphate of zinc, sulphate of alumina, and sulphate of magnesia. Various modes of procedure are described. In some of them there is combined with the "sizing" of paper pulp the precipitation among it of "filling" material, such as sulphate of barium.

### XXI.—EXPLOSIVES, MATCHES, Etc.

*Improvements in the Manufacture of Explosive Compounds.* F. W. Gilles, Cöln, Germany. Eng. Pat. 1883, 1883.

THE author of this invention proposes to manufacture explosive compounds by treating molasses by a mixture of nitric and sulphuric acids. By one method he mixes 380 grammes of raw molasses, 1,000 grammes of fuming nitric acid, and 2,000 grammes of "concentrated sulphuric acid," and washes the product several times, alternately with cold and then with warm water. "The compact nitro-molasses thus obtained is of either a gray, yellow, or whitish colour, and can be used at once as an explosive material, or it can be added to any absorbent and formed into blasting cartridges. A more powerful explosive in the fluid form is obtained from the molasses, if the same," after having had as much water as possible evaporated off from it, "is brought, by being treated with brown peroxide of lead and sulphide of carbon, or by passing oxygen through the mass, or by addition of oxygen, to a composition corresponding to 30 per cent. carbon, 20 per cent. oxygen, and 50 per cent. water chemically combined, the mineral components not being" counted. It is when the molasses contains more than the just stated proportion of oxygen that it is to be treated by peroxide of lead and bisulphide of carbon; when it contains less than that proportion of oxygen it is to be treated by oxygen gas, forced into it under pressure in closed vessels. "In all cases, the proportion of carbon to oxygen should be in the ratio of 3 to 2." When the molasses is treated by peroxide of lead and bisulphide of carbon, these bodies are added to the molasses in open vessels, and the mixture is allowed to ferment, for periods varying, with the temperature, from 24 hours, which are sufficient when the mixture is maintained at a temperature of  $70^{\circ}\text{C}$ ., to 28 days, which is

the period required when the temperature is below  $18^{\circ}\text{C}$ . The "prepared" molasses is then nitrated as above described for raw molasses. "The fluid nitro-molasses thus obtained when heated slowly boils at between  $180^{\circ}$  and  $200^{\circ}\text{C}$ ., and detonates between  $220^{\circ}$  and  $250^{\circ}\text{C}$ . It can be mixed with any absorbents, as for instance," kieselgühr. For blasting purposes, the inventor recommends various mixtures of nitro-molasses with sawdust, tan, or bran which has been previously impregnated with nitrate of potash.

*Improvements in the Manufacture of Explosive Compounds.* E. Turpin, Paris. Eng. Pat. 2139, 1883.

THE object of this invention is to manufacture "an explosive compound which acts similarly to ordinary gunpowder, but with about three times greater power, provided the ignition of the charge be effected simply by fire, or which produces powerful explosions even in the open air, similar to those produced by dynamite, if the ignition of the charge be effected by the initial explosion of a suitable detonator, such as one having a priming consisting of a grain of fulminate of mercury." The said explosive compound is formed by mixing together about 50 parts of pulverised chlorate of potash and 20 parts of ordinary coal tar, adding from 1 to 10 per cent., according to the degree of fluidity of the tar used, "of a suitable porous absorbent substance, such as powdered wood charcoal, silica, kieselgühr, randanite, and the like." "If it is desired to increase the sensitiveness of the compound, from 1 to 10 per cent. of permanganate of potash is substituted for from 1 to 10 per cent. of the chlorate of potash;" in the reverse case, for part of the chlorate of potash nitrate of potash is substituted.

### XXII.—GENERAL ANALYTICAL CHEMISTRY.

*On the Estimation of Carbon in Cast Iron and Steel.* G. Zabinsky. Journ. d. russ. phys.-chem. Gesellschaft 1883 (1) 410; and Berl. Ber. 16, 2318.

IN place of a solution, the author employs for the decomposition of carboniferous iron a dry mixture of copper sulphate and sodium chloride, which is prepared by the evaporation of 100c.c. of a solution containing 20grms. of each salt. For every gram of finely-divided iron 20grms. of the mixture are taken; enough water is added to form a pasty mass when stirred, and the whole is triturated in a glazed mortar until hard particles are no longer detected under the pestle. The pasty mass is then brought into a glass vessel, the mortar rinsed with a solution of ferric chloride, and the mixture gently warmed, at first alone, and finally with hydrochloric acid. The residue of pure carbon is then transferred to an asbestos filter. The whole operation takes from 2 to  $2\frac{1}{2}$  hours. The combustion of the residue gives perfectly satisfactory results. S. Y.

### New Books.

**BLEACHING, DYEING, AND CALICO PRINTING.** With Formulae. London: J. and A. Churchill, 11, New Burlington Street. 1884. (One of Churchill's Technological Handbooks.) Edited by Mr. JOHN GARDNER.

THE book is an octavo volume, bound in cloth, and contains 203 pages and five illustrations. The matter is distributed in four chapters, these being followed by a short appendix. Chap. i., bleaching, 33 pages; Chap. ii., dyeing, 28 pages; Chap. iii., calico printing, 22 pages; chap. iv., dyestuffs, 58 pages; the appendix occupying two pages, and the alphabetical index seven pages. Since in this small work the attempt is made to deal with dyestuffs, as well as their employment in the tinctorial arts, it is scarcely necessary to say the treatment of the

subject is very concise. Receipts are proportionately somewhat numerous, and, in the main, the object of the work seems to be to give concise practical rules for bleaching, dyeing, and calico printing, though here and there opinions on certain specific points are given and supported by authoritative evidence, and these opinions will be doubtless of considerable value.

TECHNISCH-CHEMISCHES JAHRBUCH, 1882-1883: Ein Bericht über die Fortschritte auf dem Gebiete der chemischen Technologie von Mitte 1882 bis Mitte 1883. Herausgegeben von Dr. RUDOLF BIEDERMANN. Fünfter Jahrgang. Mit 337 in den Text gedruckten Illustrationen. Berlin: Verlag von Julius Springer, 1884.

AN Svo volume, bound in cloth, 608 pages and 337 wood engravings, tables of contents at the beginning, and double alphabetical index of names of authors and of subject matter at the end. The price of the work is 12m. (12 shillings). As regards its plan, it is a model of skilful arrangement, and follows, to a considerable extent, the method of the German Patentblatt und Die Chemische Industrie. The contents are arranged in the following order: (A) General literature of statistics. (B) Chemical technology. Metallurgy, pages, 10 to 62; salt and soda, 63 to 73; potassium compounds, 89 to 90; ammonia, 91 to 98; alkaline earths, 101 to 107; alum, 110 to 114; glass, 114 to 125; pottery, 125 to 151; building materials, limes, cements, etc., 151 to 166; explosives, 166 to 184; fuel and gas, 184 to 228; sugar, 228 to 273; starch and starch-sugar, 273 to 286; wine, 286 to 303; beer, 303 to 325; spirits, 325 to 357; fats, oils, soap, etc., 357 to 373; water, 373 to 400; foods, etc., 400 to 436; manures, 436 to 445; tanning, 445 to 456; glue, 456 to 458; dyestuffs, inorganic colours, and pigments, 458 to 462; tar-colours, 462 to 500; textiles, 500 to 504; paper, 504 to 511; photography, etc., 511 to 515; organic acids, 515 to 518; alkaloids, 518 to 525; apparatus, 525 to 546. Review of new books in the period stated, 579 to 597. This Bücherschau (review of new books) is certainly a novel and useful feature in a work of this kind.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1883.

5832 N. L. Pouschkareff, Moscow. Improvements in the means and apparatus for lighting by means of hydrocarbon vapour, part of which apparatus is also applicable for storing inflammable liquids generally. December 21  
5841 C. D. Abel, London. Improvements in desiccating woods. Communicated by J. A. Koch, Galveston, U.S.A., and W. Herre, Berlin. December 22  
5846 T. W. B. Munford and R. Moody, Victoria Docks. Improvements in apparatus for grinding, crushing, or reducing to powder ores, quartz, or other like substances. December 22  
5847 A. P. Price, London. Improvements in recovering and obtaining tin from tinned metallic surfaces. December 22  
5849 P. M. Justice, London. Improvements in the manufacture of alkalies and alkaline salts. Communicated by S. G. Thomas, Algiers. December 22  
5855 C. D. Abel, London. Improvements in the impregnation of wood and textile fabrics with protective or preservative substances. Communicated by J. A. Koch, Galveston, U.S.A., and W. Herre, Berlin. December 21  
5844 G. Hand-Smith, Chelsea. Improvements in sinking or fixing colours, marks, or designs into or on marble, wood, ivory, and other materials, and in apparatus employed therein. December 26  
5862 G. Hand-Smith, Chelsea. Improvements in the manufacture of white lead and in apparatus employed therein. December 26  
5867 H. Brunner, Widnes. Improvements in the manufacture of baskets, skeleton barrels, or crates for carrying acid carboys or other merchandise requiring a strong but not water-tight casing or package. Communicated by C. Garneri, Paris. December 27  
5868 W. Weldon, Burstow. Improvements in and relating to the manufacture of chlorine. December 27  
5873 N. McFarlane Henderson, Broxburn. Improvements in obtaining oil and gas from minerals, and in apparatus therefor. December 27

5878 J. Jameson, Newcastle-on-Tyne. Improvements in the preparation of safety paper. December 27  
5886 F. C. Glaser, Berlin. Improvements in the process for treating zinc ores. Communicated by G. v. Kramsta'sche Erben and R. Wiester, Kattowitz, Germany. December 28  
5891 J. Fordred, Tottenham. Improvements in the manufacture of German or dried yeast, part of which improvements is applicable to the production of vinegar. December 28  
5893 J. Inray, London. An improvement in apparatus for evaporating, distilling, or concentrating liquids. Communicated by H. Egells, Berlin. December 28  
5903 J. McCulluch, and H. McVicar, Calderbank, N.B. Improvements in obtaining oil and other products from minerals and in apparatus therefor. December 28  
5914 G. A. Dick, London. Improvements in the manufacture of metallic alloys or compounds. December 29  
5938 E. Morewood, Llanelly. Improvements in coating metal plates. December 31  
5954 W. Green, St. Lawrence. Improvements in the treatment of mineral oils in combination with other matters, and producing therefrom soap, candles, and other articles. Dec. 31  
5958 C. F. Claus, London. Improvements in obtaining from alkali-waste either free sulphur, or free sulphur and sulphurous acid, or free sulphur and sulphuretted hydrogen. December 31  
5959 C. F. Claus, London. Improvements in obtaining sulphur from sulphuretted hydrogen. December 31  
5960 C. F. Claus, London. Improvements in the treatment of mixtures of sulphuretted hydrogen and other gases to obtain the sulphur of their sulphuretted hydrogen as sulphurous acid. December 31  
5962 H. J. Haddan, London. An improved process and apparatus for the manufacture of white lead. Communicated by F. Schmoll, Cologne. December 31  
5965 G. W. von Nawrocki, Berlin. Improvements in bleaching leather and tanned hides. Communicated by G. Levinstein, Wiesbaden. December 31  
5969 R. Baynes and J. Fearnside, jun., and W. P. Thompson, Liverpool. Improvements in the bleaching or purification of petroleum, and of other distillable oils. December 31  
5974 C. B. Warner, London. Improvements in the manufacture of artificial bone, ebony, marble, porcelain, and other substances. Partly communicated by Ljubomir Mestaniz, New York. December 31  
5979 A. J. Boulton, London. Improvements in regenerative coke furnaces. Communicated by the Schlesi'sche Kohlen und Koks Werke, Gottesberg, Germany. December 31

1884.

16 J. Hanson, Bingley. Improvements in apparatus for extracting ammonia and other impurities from coal gas. January 1  
32 H. H. Lake, London. An improved compound for plastering or stucco work. Communicated by H. E. Scales, Newton, U.S.A. January 1  
48 J. G. Willans, West Hampstead. Improvements in the manufacture of aluminium. January 1  
49 J. G. Willans, West Hampstead. Improvements in obtaining volatile products from coal. January 1  
71 J. Armstrong, Clapham. Improvements in the manufacture of beer or other beverages, and extracts or products to be employed in such manufacture, and for similar purposes. January 1  
72 A. C. Henderson, London. An improved process for bleaching rags, tissues, and textiles of all kinds, and paper pulp. Communicated by L. de Roussen, Paris. January 1  
92 S. C. Dean, Fulham. Purifying sewer gas and mephitic vapour. January 1  
93 S. C. Dean, Fulham. Purifying sewage and foul waters. January 1  
94 R. Nicholls, Hendon. Improvements in the treatment with sanitary objects of human excreta and other putrescible matter, and in apparatus and means employed in the conversion of the same for manurial purposes. January 1  
113 B. C. Molloy, M.P., London. Improvements in amalgamating gold and other metals, and in the apparatus employed therein. January 1  
151 J. H. Johnson, London. Improvements in the manufacture of paper. Communicated by J. A. Mayrneis, Paris. January 1  
153 K. Stone, London. Improvements in the manufacture of cement, bricks, tiles, and similar articles, which are also applicable for smelting, heating, and burning purposes generally, and in machinery and apparatus for carrying the same into effect. January 1  
203 H. R. Snelgrove, Clapham. Improvements in apparatus for purifying and increasing the illuminating power of coal gas. January 1  
209 H. J. Haddan, Westminster. A new or improved process for producing assimilable phosphates from phosphoric slags or residues obtained in the manufacture of iron and steel. Communicated by A. W. B. S. van Oldruitenborgh, Liège, Belgium. January 1  
221 D. Urquhart, Westminster. Improved means for suspending the corrosive action of acids and acid mixtures, more particularly applicable to the manufacture of disinfecting compounds and polishing powders. January 1  
222 Professor A. K. Huntington, London. An improvement in the manufacture of tungstic acid and its compounds. January 1  
224 Professor A. K. Huntington and J. Humphrys, London. An improvement in the treatment of scrap zinc for the recovery of zinc and solder. January 1  
338 C. M. Pielticker, Kilmarnock. Improvements in the production of steel and other metal wire, plates, rods, bars, and

rails, and also in apparatus connected therewith. Partly communicated by Dr. F. C. G. Müller, Brandenburg, Germany. January 2

351 H. Knowles, Woodville. Improvements in continuous and semi-continuous action kilns for burning bricks, pottery-ware, or lime, or for other like purposes. January 2

352 H. Knowles, Woodville. Improvements in ovens or detached kilns for burning bricks, potteryware, or lime, or for other like purposes. January 2

418 C. J. Mountford, Birmingham. Improved manufacture of fire-proof paints. January 2

443 C. E. Bell, Durham. Improvements in apparatus for coking and distilling coal. January 2

474 H. Knowles, Woodville. Improvements in fireplaces for heating kilns, pottery ovens, glass furnaces, or other heating purposes. January 2

475 H. Knowles, Woodville. Improvements in the construction of kilns, pottery or coke ovens, glass furnaces, or like structures. January 2

491 B. P. Walker, Birmingham, and J. A. B. Bennett, King's Heath. Improvements in self-acting retorts for the distillation of solid substances. January 3

493 J. Hingworth, Batley. An improved method of and apparatus for treating fibres, rags, and woven fabrics. January 3

551 L. A. Groth, K.G.V., London. A new and improved process and apparatus for the extraction of metals from their alkaline combinations. Communicated by R. Grätzel, Hanover, Germany. January 3

552 L. A. Groth, K.G.V., London. A new and improved method of extracting phosphates from the phosphated slags that are produced by the basic Thomas and Gilchrist process of making fluid steel. Communicated by R. Schliwa and A. Schliwa, Dortmund, Germany. January 3

579 M. Williams, Wigan. Improvements in the manufacture and preparations of drying oils. January 3

603 Sir F. C. Knowles, Bart, Ryde. A new or improved method of treating sulphides and oxides of metals and obtaining products therefrom. January 3

637 W. E. Leyland, St. Helens. Improvements in the construction of apparatus for consuming smoke and sulphurous or other noxious vapours. January 4

509 E. Crowe, Middlesbrough. Improvements in apparatus for controlling and regulating the production of gas in gas producers. January 4

727 J. Kay, Bury. Improvements in the process and apparatus for manufacturing white lead. January 5

751 J. Wheeler, Hiraconbe. Improvements in the manufacture of miscible tar. January 5

753 J. Sansom, Glasgow. An improved oil compound for use in quelling waves at sea. January 5

761 R. Cooper, Over Darwen. Improvements in apparatus for straining pulp used in the manufacture of paper. January 5

761 A. G. Southby, Jersey. Improvements in the mode of and apparatus for cleansing beer. January 5

774 G. Dunbar, Malin, Bingley. Improvements in washers for the purification of gas, which apparatus is to be called, "The Malin Self-acting Tower Washer." January 5

787 W. G. Strype, Wicklow. Improvements in the treatment of blood to prepare it for use as a manure, or for other purposes. January 5

816 Dr. Les Gans, Frankfort-on-Main, and Dr. Meinhard Hoffmann, Mainkur, Germany. The manufacture of new colour-yielding products, and of colouring matter therefrom. January 5

852 A. J. Shilton, Birmingham. A new disinfectant, called "Affinitan." January 7

879 E. Loeflund, Stuttgart, Germany. An improved process for preserving milk or cream. January 7

890 J. Dearnley Wilson, A. Ambler, and J. Charnock Marshall, Sowerby Bridge. An improved process or means for extracting tannin or tannic acid from mirabalan nuts and other vegetable products. January 7

895 W. Beatson, Rotherham. An improved method of obtaining tin from tin scrap. January 7

903 J. Huray, London. An improvement in the manufacture of sulfoconjugate violet dyes. Communicated by La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis, and Messrs. Poirrier and A. Itosenstahl, all of Paris. Complete specification. January 7

961 W. Martin, Milford Haven. An improved process for the manufacture of ammoniacal phosphates or phosphites. January 8

981 H. J. Haddan, London. A new or improved manufacture of binitro-hydrocellulose, and of explosives containing the same. Communicated by J. Hagemann, St. Anton, Tyrol. January 8

997 P. Barry, Tottenham. Improvements in iron manufacture. January 8

1024 E. Edwards, London. A new or improved explosive material to be used in blasting in mines and quarries. Communicated by L. Hensschen, Montjean, France. January 8

1031 W. P. Thompson, Liverpool. A new or improved colouring matter, and process for obtaining the same. Communicated by M. E. Savigny, New York. Complete specification. January 9

1032 W. P. Thompson, Liverpool. A new or improved colouring matter, and process for obtaining the same. Communicated by M. E. Savigny, New York. Complete specification. January 9

1074 J. P. Griess, Burton-on-Trent. Improvements in the manufacture or production of colouring matters from the tetrazo compound of benzidine-di-sulphonic acid. January 9

1079 G. Tidcombe, junior, Watford. Improvements in the

construction of strainers used for straining pulp in the manufacture of paper and paper-boards, and preparing "half-stuff" from wood, straw, and other materials for straining, clearing, or separating the shaves and other impurities from the same. January 9

1092 Major O. Glynn, Bolitho, Penzance. Improvements in the separation of ores and earthy substances. January 9

1099 J. P. Griess, Burton-on-Trent. Improvements in the manufacture or production of colouring matters obtained from sulpho-derivatives of benzidine, and in the preparation of such sulpho-derivatives. January 9

1129 R. Jardine Gibson, Dundee. Improvements in treating jute and other fibrous substances preparatory to dyeing the same. January 10

1198 H. Stier, Zwickau, Germany. Improvements in the treatment of carbonaceous substances in ovens or furnaces for the conversion thereof into combustible and other products. January 10

1223 T. Parker, Wolverhampton. Improvements in the production of yellow metal, partly applicable also to the founding of brass and bronze generally. January 11

1239 T. Ferneley Wiley, Hammersmith. Improvements in apparatus for enriching illuminating gas. January 11

1260 E. R. Southby, London. Improvements in treating grain for brewing and analogous purposes, and in apparatus therefor. January 11

1279 F. Hille, Chiswick. Improvements in treating sewage, and in disposing of the sludge by manufacturing artificial manure from the same. January 11

1291 C. Rennie Cowie, Glasgow. Improvements in the manufacture of artificial stone. Complete specification. January 12

1308 G. Hitchen, Darwen. Improvements in calcining furnaces for recovering soda ash. January 12

1340 R. Smith Casson, Brierley Hill. Improvements in the treatment of coke and peat. January 12

1341 S. Gilchrist Thomas, London. Improvements in the manufacture of phosphates. January 12

1342 S. Gilchrist Thomas, London. Improvements in the manufacture of alkalies and phosphates. January 12

1343 S. Gilchrist Thomas, London. Improvements in the manufacture of alkaline silicates and other alkaline salts. January 12

1380 F. McNamee, Liverpool. Improvements in the manufacture of spirits or alcohol, and of manure from certain waste materials. January 14

1112 L. Roth, Wetzlar, Germany. An improved manufacture of cement. Complete specification. January 11

## FRANCE.

1883.

154902 Vorster and Grunberg. A process for removing ammonia from lighting and other gas, and obtaining sulphate and other salts of ammonia thereby. April 16

154920 Armour. Treatment of the residues or waste of collieries, of peat, and other coaly substances. April 17

154924 Appert Brothers. Moulding glass and dividing cast glass into various shapes and sizes. April 17

154927 Charmes, Montpelier. A tubular perforator for employing sulphide of carbon. April 17

154928 Schneider. A liquid for destroying the phylloxera. April 18

154930 Fanchoux, Loos. Obtaining metallic bases or oxides. April 18

154935 Stier. Kilns for obtaining coke, and for distilling purposes. April 18

154939 Dannenberg. A kiln with a gas-chamber and movable sole for burning bricks, pottery, and calcining lime, cement, and strontianite. April 18

154947 Hulin. Processes and apparatus for the simultaneous production of coke and combustible gas. April 18

154952 Gandel and Mrs. Fiaux. Applying Bunsen burners of sulphate of baryta, strontian, and other infusible substances to incandescent lamps. April 18

154979 Bang and Sanguinetti. A diffusion process for extracting oil and fat bodies. April 19

154980 Canet, Toulouse. Apparatus for fermenting alcoholic beverages. April 17

154991 Breyer. Obtaining micro-membranes for removing microscopic organisms from liquids and gases. April 20

154997 The Panclastite Company. A single or double-acting explosive, with a base of bitumen or tar. April 18

155006 Stocker. An incombustible cellulose-plastic product. April 20

155011 Blitz. Obtaining a kind of fibrous, ligneous, white or coloured cellulose resembling rag pulp, etc. April 20

155026 Pictet and Brelaz. Obtaining chemical wood pulp. April 21

155032 Hyam and Howell. Processes and apparatus for tanning hides, leather, etc. April 21

155034 Dittler and Company. Obtaining yellow and red colouring substances. April 21

155018 Delaine, Fosseux. Extracting beet-juice. April 25

155053 Sezille, Leballois-Perret. Obtaining maize yeast by acid saccharification. April 23

155058 Jameson. Dry distillation. April 23

155070 Mignon and Rouart. Apparatus for the production of cold. April 21

155080 Minguet and Jolibois, Paris. A liquid atomiser for distillation. April 21

- 155085 Weiler and Company. Separating paratoluidine from orthotoluidine, and also aniline and paratoluidine, by means of phosphates and arseniates. April 24  
 155091 Clannond. Obtaining hydrogen. April 24  
 155098 The Nickel and White Metal Foundry. Manufacturing pure and malleable nickel and cobalt and their alloys with iron. April 24  
 155107 Young and Beilby. Treatment of coal and other substances for obtaining ammonia or ammoniacal compounds, and heating gas; also apparatus belonging thereto. April 25  
 155108 Marchand. Obtaining bioxides of barium and calcium. April 25  
 155113 Deinhardt. Boiling hops. April 25  
 155116 Laguarigne De Survilleir, St. Pierre. An electric sifter for extracting the magnetic oxidulated iron ore  $Fe_2O_3$ , discovered in the ferruginous sand of the isle of Martinique and other colonies. March 21  
 155127 Gibson, junior, and Platt. An apparatus for soaping or ungreasing and dyeing tissues. April 25  
 155151 Julien, Castres. A mechanical process for extracting burdocks, grain, straw, and other vegetable remains from textiles. April 30  
 155158 Goutrand. A solution of camphor in alcohol for destroying the phylloxera. April 28  
 155174 Krupp. Obtaining compound plates and other products by welding hard iron and steel on soft iron and steel. April 30  
 155181 Spielhagen. Soap making. April 30.

#### Certificates of Addition.

- 154114 Possoz. Extracting sugar from molasses, etc. April 17  
 150936 Lissagaray and Leplay. Extracting tallow for obtaining oleo-margarine. April 18  
 138841 Richerol. A mixture called "alunoxium," for the manufacture of pipes, pottery, etc. April 19  
 118958 Scheibler. Separating sugar from molasses and syrup by production of saccharate of strontia. April 24  
 151671 Jameson. Obtaining coke. April 24  
 132479 David. An economical production of active oxygen and peroxide of hydrogen. April 30  
 150835 Dubus, Coget, and Company. Extracting fat, gelatinous, or gummy substances from tissues, etc. April 26

#### UNITED STATES.

- 289513 I. Levinstein, Manchester, England. The manufacture of yellow colouring matter. April 5, 1883  
 289515 Dugald McEchran, Greenock, Scotland. An apparatus for separating iron from charcoal, etc. December 20, 1881  
 289587 E. Warne, Easton, Pa. A method of and apparatus for reducing and disintegrating ores. February 25, 1882  
 289588 A. J. Weeks and J. E. Weeks, Littleton, N.H. A process of tanning. September 11, 1883  
 289613 O. Bredt, Barmen, Germany. The manufacture of red colouring matter. June 12, 1882  
 289706 J. E. Pontefract, Pittsburg, Pa. A process of and apparatus for distillation. October 15, 1883  
 289717 E. Sanser and M. Haller, Cincinnati, Ohio. A device for cooling beer. June 15, 1883  
 289755 S. R. Divine, Loch Sheldrake, N.Y. A process of preparing explosive compounds. July 23, 1883  
 289756 S. R. Divine, Loch Sheldrake. An explosive compound. July 23, 1883

- 289757 S. R. Divine, Loch Sheldrake. An explosive compound. July 23, 1883  
 289758 S. R. Divine, Loch Sheldrake. An explosive compound. July 23, 1883  
 289759 S. R. Divine, Loch Sheldrake. An explosive compound. July 23, 1883  
 289760 S. R. Divine, Loch Sheldrake. An explosive compound. August 1, 1883  
 289761 S. R. Divine, Loch Sheldrake, and A. C. Rand, New York. A method of preparing blasting cartridges. August 22, 1883  
 289762 S. R. Divine, Loch Sheldrake. An explosive compound. August 8, 1883  
 289763 S. R. Divine, Loch Sheldrake. An explosive compound. August 8, 1883  
 289761 S. R. Divine, Loch Sheldrake. A blasting cartridge. August 7, 1883  
 289765 S. R. Divine, Loch Sheldrake. A composition for preparing explosive compounds. August 7, 1883  
 289781 E. N. Riotté, New York. A process of obtaining precious metals from ores by amalgamation. July 13, 1882  
 289785 J. Stuart, Tracer, Iowa. An evaporating apparatus. October 17, 1883  
 289788 H. Ujhely, Vienna. A process of decolorising and deodorising heavy mineral oils. February 24, 1883  
 289791 Adam Wingard, San Francisco, Cal. A dry-ore pulveriser and concentrator. September 16, 1882  
 289836 J. B. Houson, San Francisco. A process of and apparatus for obtaining boracic acid from native borate of lime. January 19, 1883  
 289842 E. J. Jerzmanowski, New York. Apparatus for producing gas. April 3, 1883  
 289887 J. Butler, Kenosha, Ohio. A coke-oven. June 13, 1883  
 289914 E. J. Jerzmanowski, New York. A process of producing combustible gas. March 27, 1883  
 289939 J. Stickle, Denver, Colorado. A process of moulding and treating slag for paving and other purposes. March 23, 1883

### COUNCIL.

*President:* Walter Weldon, F.R.S.

*Vice-Presidents who have filled the Office of President:*

Sir Frederick Abel, C.B., D.C.L., F.R.S.  
Professor H. E. Roscoe, Ph.D., LL.D., F.R.S.

*Vice-Presidents:*

I. Lowthian Bell, F.R.S.	David Howard.
George E. Davis.	E. K. Muspratt.
J. H. Gilbert, D.C.L., F.R.S.	H. Lee Pattinson.
F. H. Gossage.	W. H. Perkin, Ph.D., F.R.S.
D. B. Hewitt, M.D.	Prof. James Dewar, F.R.S.

*Ordinary Members of the Council.*

Eustace Carey.	John Pattinson.
Alexander M. Chance.	B. S. Proctor.
Prof. Chas. Graham, D.Sc.	R. Angus Smith, Ph.D., F.R.S.
Peter Griess, Ph.D., F.R.S.	John Spiller.
James Maclear.	John Williams.
R. Messel, Ph.D.	P. J. Worsley.

With the Chairmen and Secretaries of Local Sections.

*Honorary Treasurer:*

E. Rider Cook, East London Soap Works, Bow, E.

*Honorary Foreign Secretary:*

Ludwig Mond, Winnington Hall, Northwich.

*General Secretary:*

Charles G. Cresswell, Palace Chambers, 9, Bridge Street, Westminster.

### NOTICES.

#### ANNUAL GENERAL MEETING.

The next Annual General Meeting of the Members of the Society of Chemical Industry will be held at Newcastle-on-Tyne, in July.

It is proposed that at this meeting, after the transaction

of the ordinary business of the Society, and an address from the president, a discussion shall take place on all the more important of the proposed methods for the utilisation of the condensable products obtainable from coal used in the manufacture of coke, coal used in blast furnaces, and coal used as fuel. Members who desire to read papers on any branch of this subject are requested to communicate with the general secretary. Each paper should be of such length that its reading shall not occupy more than twenty minutes.

It is intended that the members attending the meeting shall have an opportunity of dining together, and it is expected that they will be invited to visit various important chemical and other works.

At a meeting of the Council of this Society, held on 21st December, 1883, it was resolved:—

1. That after December, 1883, the price of the Society's Journal to non-members be 30s. per annum, and that an announcement to that effect be printed on the cover of the Journal.

2. That the price of sets or annual volumes of the Journal to members of this Society be 21s.

3. That the price of single copies of the Journal be 2s. 6d. each to members only, and that no single copies be sold to the outside public at all.

4. That due notice being given by the Secretary, the issue of the Journal shall cease to those members who have not paid their subscriptions for 1883, commencing with the number for January, 1884.

5. That, due notice being given by the Secretary, those gentlemen who have failed to pay their subscriptions for 1882 and 1883 shall cease to be members of this Society after January 21st, 1884.

Members are requested to notify change of address as promptly as possible to the General Secretary and to the Honorary Secretary of the Section to which they belong in order to insure receipt of the Society's journal.

Members will please to take notice that the Annual Subscription of £1 1s. for 1884 is now due, and should be forwarded to the Hon. Treasurer, to whom also cheques and orders should be made payable.

The Proceedings of the First General Meeting (1881) of the Society of Chemical Industry have been reprinted in such size and style as to permit of their being bound up with the first volume of the Journal. Copies of the reprinted Proceedings will be forwarded by the Publishers on receipt by them of twelve penny stamps for each copy required.

Numerous inquiries have been made for complete sets of the Journal for 1882. Some of the numbers for that year are out of print. Members who have not the volume for 1882, and wish to obtain it, are invited to signify that wish to the Secretary as early as possible. If a sufficient number of applications for the complete set are received, the missing numbers will be reprinted.

## LIST OF MEMBERS ELECTED FEBRUARY 22nd, 1884.

James Dunnachie, Glenboig, near Coatbridge, N.B., fire-clay manufacturer.  
 James Middleton, 179, West George Street, Glasgow.  
 Alexander Crum, M.P., Kelburne, Fairlie, Greenock, calico printer.  
 J. B. Hutcheson, University of Glasgow, chemist.  
 Captain H. A. Gadsden, 19, Australian Avenue, London, E.C., merchant.  
 Alexander Whitelaw, 87, Sidney Street, Glasgow, soap manufacturer.  
 R. Cameron, Priory Lodge, Blantyre, Lanarkshire, manufacturing chemist.  
 John Addie, Langloan Ironworks, Coatbridge, N.B., iron-master.  
 H. Pickens, Prussiate Works, Droylsden, Manchester, prussiate manufacturer.  
 H. M. Hastings, 51, Edith Road, West Kensington, W., analyst.  
 Edward Sykes, 10, Hill Street, Seedley, Pendleton, Lancashire, chemist.  
 John Blair, Irvine Bank Chemical Works, Kilmarnock, N.B., manufacturing chemist.  
 J. B. Binks, 18, Esk Street, Silloth, Cumberland, analyst.  
 W. Elborne, the Owens College, Manchester, lecturer on Pharmacy and Materia Medica.  
 Dr. R. Parkinson, Sun Bridge Buildings, Bradford, Yorkshire, pharmaceutical chemist.  
 William Crowther, Field House, Gomersal, Leeds, manufacturing chemist.  
 N. L. Wilputte, 13, Park Road, Ebbw Vale, Monmouth, manager of coke ovens.  
 F. Burton, 2, Green Street, Bethnal Green, E., manufacturer of dyestuffs.  
 Edward Brooke, Oakley House, Edgerton, Huddersfield, manufacturer of fire-clay.  
 F. Oliver, 70, Winchester Street, South Shields, analyst.  
 Jas. Keen, 47, Croft Terrace, Jarrow-on-Tyne, assistant manager of rolling mills.  
 Jno. Gardner, 3, Hanover Street, Hanover Square, W., professional chemist.  
 R. H. Bow, 7, South Gray Street, Edinburgh, civil engineer.  
 J. Moffatt-Johnston, Young's Paraffin Company Limited, Bathgate, N.B., chemist.  
 Shackleton Hallett, 1, Hare Court, Temple, E. C., barrister-at-law.  
 U. Jeanneret-Grosjean, 97, Euston Road, London, N.W.  
 Ernest Solvay, a Bruxelles, chemical manufacturer.  
 Prosper Flanrez, 9, Rue Moris, a Bruxelles, chemical engineer.  
 Alfred Solvay, Boitsfort, Belgium, chemical manufacturer.  
 Louis Smet, 217, Chaussee de Vleurgat, Brussels, chemical manufacturer.  
 Dr. F. von Heyden, 6, Leipsiger Strasse, Dresden, Germany, manufacturer of salicylic acid.  
 W. McFarlane, Crosslee House, Thornliebank, N.B., manager calico printworks.  
 Dugald Clark, Crown Ironworks, N. Woodside Road, Glasgow, engineer.  
 A. Macalister, Clyde Chemical Works, Old Kippoch Hill Road, St. Rollox, Glasgow.  
 Dr. Edmund Ronalds, Bonnington House, Edinburgh.  
 Robert Orr, Linenhatch Chemical Works, Falkirk, N.B., manufacturing chemist.  
 J. Westall King, 12, Claremont Terrace, Glasgow, chemical manufacturer.  
 Charles M. King, Campsie Alum Works, Lennoxton, N.B., alum manufacturer.  
 J. E. Stoddart, Clyde Lead Works, Cornwall Street, Glasgow, manufacturing chemist.  
 A. Leamouth Adam, 18, Robertson Street, Greenock, N.B., analyst.  
 Professor A. Crum Brown, 8, Belgrave Crescent, Edinburgh, professor of chemistry.  
 C. A. Fawsitt, 1, Maule Terrace, Partick, Glasgow, chemist.  
 B. H. Remmers, 189, St. Vincent Street, Glasgow, chemical engineer.  
 John Riley, Thornliebank, near Glasgow, assistant manager of printworks.  
 George Craig, Lugar Ironworks, Cumnock, N.B., chemist.  
 Samuel Rivett, Gale Printworks, Littleborough, Manchester, manager.  
 J. W. Pratt, Runcorn Soap and Alkali Company, Runcorn, technical chemist.  
 Charles Mook, Douglasshall, Westeregeln, Prussia, director of alkali works.  
 John Walton, Hall's Wharf, Victoria Docks, E., manager chemical works.  
 Carl Wessel, Bernburg, Anhalt, Germany, soda maker by Solvay's process.  
 Alexander Dempster, Elland, Yorkshire, gas engineer.  
 W. B. Mason, 17, Derby Street, Bolton, pharmacist.  
 Johann Klein, J. Beckers, Frankenthal, Rheinpfalz, Germany.  
 J. W. Harker, 13, Billiter Street, E.C., engineer and brass-founder.  
 D. Crawford, Glengowan Printworks, Caldererux, by Glasgow.  
 Lawrence Heap, Stacksteads, near Manchester, manufacturing chemist.  
 A. H. Elliott, School of Mines, Columbia College, New York, U.S.A., chemist.  
 F. P. Koe, 38, King William Street, London, E.C., tar distiller.

Wm. Dicketts, 9, Mincing Lane, London, E.C., chemical merchant.  
 John Head, 12, Queen Anne's Gate, Westminster, S.W., civil engineer.  
 C. M. Blades, Stanley Mount, Northwich, Cheshire, analyst.  
 Thos. Holgate, 133, Manchester Road, Burnley, gas engineer.  
 W. A. Bryson, 20, Lomond Road, Trinity, Edinburgh, chemical engineer.  
 Saml. Kideal, University College, London, W.C., chemist.  
 W. H. Richmond, 37, Merton Road, Bootle, Liverpool, alkali manufacturer.  
 F. W. Renaut, The Cottage, Burstow-by-Crawley, Surrey, secretary.  
 Thos. Fox, jun., Court, Wellington, Somerset, woollen manufacturer.  
 Dr. A. Staub, 29, Grafton Street, Oxford Road, Manchester, chemist.  
 Wm. Tebb, 7, Albert Road, Gloucester Gate, Regent's Park, N.W.  
 P. S. Gilchrist, Exley Hall, Salterhebble, Halifax, chemical engineer.  
 Lieut.-Col. A. S. Jones, V.C., Hafod-y-Wern Farm, Wrexham, civil engineer.  
 J. R. Bennie, Kinning Park Foundry, Glasgow, chemical engineer.  
 W. J. A. Donald, 2, Belgrave Terrace, Glasgow, chemical manufacturer.  
 R. A. Inglis, Arden, Bothwell, N.B., chemist.  
 J. J. Long, Whitevale House, Dennistoun, Glasgow, match manufacturer.  
 C. Macnab, Lillyburn, Milton of Campsie, N.B., calico printer.  
 Jno. Miller, 151, Gunport Street, Glasgow, metallurgist.  
 G. D. H. Mitchell, Oakbank, Midcaldor, N.B., chemist, oilworks.  
 Jas. Murrie, Kinning Park Foundry, Glasgow, civil engineer.  
 W. Paterson, jun., 8, Claremont Terrace, Glasgow, merchant.  
 Jas. Stevenson, 27, St. Vincent Place, Glasgow, manufacturing chemist.  
 Harold Rawcliffe, Appleton Lodge, Widnes, student.  
 N. H. J. Miller, 8, Oppidans Road, N.W., assistant in Research laboratory.  
 B. Clifford Sykes, M.D., St. John's House, Cleekheaton, Yorkshire.  
 John West, Barfield House, Didsbury, near Manchester, civil engineer.  
 C. N. Cresswell, 1, Hare Court, Temple, E.C. barrister-at-law.  
 J. E. Marley, Messrs. Sproat, Marley and Company, Hebburn-on-Tyne, ironfounder.  
 Thomas Kirkham, Runcorn, Cheshire, chemical contractor.  
 W. H. Michael, Q.C., 4, King's Bench Walk, Temple, E.C., barrister-at-law.  
 Thomas Akitt, 3, Victoria Road, Lenzie, N.B., chemist.  
 Harry Chubb, 6, Prince's Square, Bayswater, London, W.  
 William Douglas, 53, Idenfield Street, Glasgow, analytical chemist.  
 Archibald Duncan, Muirpark, Renfrew, chemical manufacturer.  
 James Duncan, Cleland, Lanarkshire, medical practitioner.  
 Henry Gall, chez M.M. Pechiney et Cie, Salindres (Gard), France, chemist.  
 Joseph Hall, Eccleston Park, Prescott, Lancashire, manager of gasworks.  
 William Lawson, Bellshill, Lanarkshire, pharmaceutical and analytical chemist.  
 James MacKenzie, Athenaeum, Ingram Street, Glasgow, horn and bone merchant.  
 W. M. Miller, 10, Whitehill Street, Dennistoun, Glasgow, analyst.  
 George S. Packer, Hallside Steelworks, Newton by Glasgow, manager.  
 Thomas Poole, 25, Water Street, Liverpool, chemical broker.  
 George T. Powell, Rotherwood, Sydenham Hill, S.E., solicitor.  
 James Riley, 150, Hope Street, Glasgow, steel manufacturer.  
 Edward Rodger, 1, Clairmont Gardens, Glasgow, W.

## London Section.

Chairman: David Howard.

## Committee:

Sir F. A. Abel.	J. Messel.
E. Rider Cook.	B. E. R. Newlands.
W. Crowder.	Thos. Itoyle.
Dr. E. Frankland.	John Spiller.
Prof. Charles Graham.	G. C. Trewby.
F. Maxwell Lyte.	C. Umney.
Geo. Matthey.	J. Williams.

Local Sec.: Thos. Tyrer, Battersea, S.W.

The meetings of this Section are held on the first Monday in each month.

On March 3, the following Papers will be read—(1) "On the Manufacture of Cuprammonium and Zincammonium, and their Technical Adaptation." (2) "On the Filtration of Potable Waters." (3) "On Some Applications of Kieselsäure."

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE,  
Monday, February 4th, 1884.

MR. DAVID HOWARD IN THE CHAIR.

## ON THE DISPOSAL OF SEWAGE SLUDGE.

BY CHRISTOPHER CLARKE HUTCHINSON.

AMONG the many problems engaging the attention of sanitary engineers, that which embraces the removal and disposal of the refuse matters of a community, termed sewage, stands perhaps the most prominent. Ignorance of the principles of sanitary requirements, and of the many factors which contribute to the growth of disease resulting from the infringement of Nature's laws, is quite sufficient to account for the laxity of ideas which, even up to recent times, prevailed on this subject. But with the rapid advances of natural science those principles which are now recognised as governing health and disease were gradually developed, and we became alive to the fact that if we would be free from many forms of disease, it was essential to remove from our midst those materials which were either their direct cause or agents of transmission. It is curious to note, on a perusal of the many patented inventions bearing upon this subject, that up to even a very recent date inventors seemed to have in view the realisation of commercial profit, by the extraction of substances valuable for agricultural and other purposes, rather than the abatement of nuisance and the promotion of public cleanliness; but as communities grew, and the fallacies of such ideas were shown by the repeated failures of innumerable golden projects, many of which had for their object a goal somewhat commensurate with "the philosopher's stone" or "the elixir of life," it became generally recognised that the sewage question simply resolved itself into the disposal of the refuse and filth of our towns in the most economical and effectual manner. This is cogently expressed in the conclusions arrived at by the Committee of the Society of Arts\*: "For health's sake, without consideration of commercial profit, sewage and excreta must be got rid of at any cost." The question therefore resolves itself into disposing of this offensive matter in a manner best suited to the locality, having regard (1) to the sanitary efficiency of the means employed, (2) the economical attainment of the result, and (3) the reduction of enforced expenditure by the employment of measures of disposal affording some return of the means expended.

Prior to the passage of the Rivers Pollution Act in 1876, it was not incumbent upon every town, as specifically enforced by law, to abstain from turning direct into the nearest watercourse, without taking measures for purification, the whole of its sewage, and the onus of enforcing abatement of wholesale pollution rested with the riparian proprietor whose property might suffer deterioration. Such a means of disposal of course fulfilled no one of the above conditions; and it is only now tolerated in the case of those towns discharging their sewage into a tidal river, when it is assumed the impurities will be carried direct into the sea. How far such an assumption can be borne out may here be briefly alluded to in the case of the Thames. The metropolis is the only town on the Thames now permitted to discharge its sewage directly into the river without adopting "the best practical and available means" for its purification. The dry weather volume of sewage so discharged daily into the river, from the outfalls at Barking and Crossness, is upwards

of 125 millions of gallons, containing in suspension about 250 and in solution about 450 tons of solid matter. Now a portion of the 450 tons of matter in solution is capable of being precipitated, and doubtless by the action of oxidation as well as of actual precipitation by the fresh water of the river some portion is actually so thrown down. Consequently, it appears that from 250 to 300 tons of objectionable and putrescent solid matter, equalling about 3,000 tons of what is termed "sewage sludge," capable of depositing, are daily admitted into the river. Now if this could be carried away directly to the sea by the action of the tide, such a method of sewage disposal might—under the circumstances—not be held to be objectionable; but when we consider that the tidal outfalls are a distance of some 41 miles from the mouth of the river, it is apparent that the time occupied in reaching the sea must be considerable. It has recently been clearly shown by Professor W. Cawthorne Unwin,\* that if the travel of matter in the river were due to the upland water alone discharged into the river at Teddington, the passage of solid matter entering the Thames at Woolwich down to Sheerness would occupy about 65 days. This, he shows, is considerably modified by tidal action, but that viewed under the most favourable circumstances, the period of oscillation of a segment of sewage-laden water between the mouth of the river at Sheerness and the outfalls of the sewers is about 44 tides or 22 days. The effect of the presence of so large a volume of putrescent matter in the lower part of the river, placed under conditions favourable for deposition, can hardly be over-estimated. The clothing of the river banks with sewage mud, as well as the shoals of gelatinous sewage matter accumulating in the bed of the river, is in itself a convincing proof of the inefficiency of the disposal of the metropolitan sewage by the present tidal outfalls. How long this problem, the solution of which is not by any means overwhelming, will be permitted to rest unattacked may possibly only be determined by the occurrence in the future of an epidemic decimation, giving the necessary stimulus to more advanced metropolitan sanitary legislation, thereby removing what now exists as a blot upon the cleanliness of the largest and richest city of the world. Before entering into the details of the specific method for the abatement of the sewage difficulty now brought before your notice, it will be necessary to briefly touch upon the methods for sewage disposal now usually employed, so as to be better able to show the extent and importance of its bearing upon the whole question, irrespective of the definite system pursued.

Processes for the abatement of river pollution by sewage may be broadly grouped under two heads: (1) Processes of prevention. (2) Processes of purification.

### I.—PROCESSES OF PREVENTION.

Under this head are embraced all the various methods and contrivances for dealing with human excreta upon a distinct and separate system other than water carriage. But as this forms only a fractional part of the many elements of pollution, the alleviation it affords is only partial, while at the same time the system of water carriage has still to be resorted to. Hence it follows that, providing only for one portion of the general problem, it cannot in any case obviate a water-carried system and consequently measures of purification. How small is its preventive effect, as regards the polluting character of the remaining sewage, is shown by the table given

\* Report of the results of the Conference of Health and Sewage of Towns, 1876.

\* "On the Movement of the Water in the Tidal River with Reference to the Position of the Sewer Outfalls." By W. Cawthorne Unwin, M.I.C.E.

below, the figures in which are taken from the report of the Rivers Pollution Commission on the Mersey and Ribble basins.

AVERAGE COMPOSITION OF SEWAGE IN PARTS PER 100,000.

Description.	Solids in solution.	Organic carbon.	Organic nitrogen.	Ammonia.	Nitrogen as nitrates.	Total combined nitrogen.	Chlorine.	SUSPENDED MATTERS.		
								Mineral.	Organic.	Total.
Water-closet Towns...	72.2	4.696	2.205	6.703	.003	7.728	10.66	24.18	20.51	44.69
Midden, &c Towns...	82.1	4.181	1.975	5.435	.000	6.431	11.54	17.81	21.30	39.11

Now without entering into details of the expenditure incident to the various systems included under this head, it will be at once apparent that as the means employed do not sensibly affect the question of alleviation, it follows that the expenditure upon the process of purification, which must be employed upon the bulk of the sewage, cannot be very much (if at all) diminished, consequently such measures do not satisfy the first two of the requirements before set forth, viz.,

Years of experience under varied conditions have, however, demonstrated this process to be not altogether so free from difficulty, or so remunerative as was anticipated. In the first instance suitable land is not always procurable, then again the area required, so that the requirements of the vegetation may be considered, as well as the cleansing of the sewage, becomes enormous. From 25 to 50 persons per acre of land has been estimated, from results obtained by experience, as the correct basis of operation. Such proportions would necessitate the employment of enormous areas to be brought under irrigation culture, a few instances of which are given below:—

Town.	Population.	Area required at 1 acre=50 persons.
Leeds .....	250,000 .....	5,000
Manchester .....	300,000 .....	7,200
Glasgow .....	510,000 .....	10,200
London .....	3,500,000 .....	70,000

Nor is this alone the only difficulty. It has become from experience a well-known fact that the purifying effect of an area of land continuously used for purposes of irrigation is not lasting, and that ultimately the soil becomes so saturated that a serious nuisance, both disagreeable to the senses and injurious to health, is the result. On this head the experience of Mr. Hawksley may be quoted\*: "Water irrigation carried

FIG. 1.

(1) efficiency, (2) economy. How far it meets the remaining and minor consideration will be noticed after on.

## II.—PROCESSES OF PURIFICATION.

The means employed for the purification of water-carried sewage are all to be classed under three heads: (a) Irrigation. (b) Intermittent filtration. (c) Chemical precipitation. There are, however, instances, more particularly in later practice, and in cases which altogether depend upon the local conditions and required standard of purification, in which no one of these methods is pursued in its entirety, but an attempt is made to produce the most efficient and economical result by combining the salient advantages of two or more. It will, however, perhaps be more convenient to notice each in its entirety, so that the drawbacks and difficulties attendant may be shown.

(a)—IRRIGATION.—At first sight it would appear that under all circumstances where it was possible to procure the necessary area of land, the method of purification by broad irrigation, attaining at the first glance the double object of extreme purification and the realisation of the "mine of wealth" sewage has always been understood to contain, would be the most rational course to adopt.

on in warm weather is exceedingly unhealthy. . . . I can speak positively to it from repeated observation in different places, that the odour, particularly at night, and particularly upon damp evenings in autumn, is very sickly indeed, and that in all these cases a great deal of disease prevails. The sewage forms a deposit on the surface of the ground, that deposit forms a cake of organic matter, and that organic matter when it is in a damp state, as it usually is, gives off in warm weather a most odious stench." Evidence of a similar nature could be multiplied to almost any extent, all of which points to the conclusion that if irrigation is to be practised with any measure of success from a sanitary point of view, it becomes necessary to adopt measures for removing the putrescent solid suspended matter, either by subsidence or partial chemical treatment, in order to avoid the clogging of the pores of the ground and the formation of a film of putrefactive matter injurious alike to the health of the neighbourhood and the vegetation of the ground itself. Such being the case, it is evident measures must be adopted for the effectual disposal of the resulting accumulations of sludge by the most efficient and economical process which

\* Mr. Thomas Hawksley, C.E., evidence before committees of the House of Commons. 1870.

FIG. 2

can be employed. Both in this and the two succeeding cases such means of disposal will be considered separately. Viewed from an economical standpoint, it will be amply sufficient for the purposes of this paper to state that experience has shown that even where the local conditions are favourable no great return can be expected. "Great hopes were a few years ago entertained that in irrigation had been found the grand solution of the sewage question.

All that is changed now. Sewage farms on which immense sums of money have been expended have been reluctantly abandoned, and irrigation is no longer regarded as anything more than a means of obtaining a good effluent at a moderate outlay.\*

(b) **INTERMITTENT FILTRATION.**—The experiments of Dr. Frankland, published in the First Report of the Rivers Pollution Commissioners of 1868, clearly show that the passage of sewage water *through* a properly prepared filtration area of soil effects a purification far in excess of the effect which would be produced by irrigation *over the surface* of the same area. It is further shown that it is possible, by means of an acre of properly drained and prepared soil, six feet deep, *used intermittently*, to effect the purification of the sewage resulting from a population of 3,300 persons, sufficient to enable the water to be used again for all but domestic purposes, the result of such treatment being that, by means of oxidation, nearly the whole of the organic matter in *solution* is transformed into innocuous inorganic salts. It is, however, manifestly essential that as the continued efficiency of the same area depends entirely upon its thorough aeration during intervals of rest, it should be kept in such a condition that it can readily absorb a fresh supply of oxygen to bring to bear upon a further quantity of sewage. It therefore follows that to maintain the porosity of the soil it is essential to keep the suspended decaying organic matter contained in the sewage from blocking up the pores of the soil. This can only be effected by its interception; and as a consequence, as is the case in irrigation, whatever be the means employed there will be the inevitable accompaniment of sludge accumulation. In the report before referred to this is pointed out as follows: "It is not unlikely that the operation, involving as it does the exposure of large and offensive filtering beds to the air, would be itself attended with much serious nuisance. The previous treatment of the sewage by one of the chemical processes already described would, however, obviate this liability to nuisance, whilst it would probably reduce by one-half the size of the filter necessary for cleansing a given volume of sewage. Such a combination of a chemical method with intermittent filtration offers the most hopeful process." It therefore appears that this method, like irrigation, cannot be efficiently used without some means for the disposal of the sludge. Several applications of this process could be alluded to—for instance, the works of the Croydon Rural Sanitary Authority, designed by Mr. Baldwin Latham, in which case the filtration area is so disposed, both in size and treatment, as to be brought under cultivation as a sewage farm, and thus return some portion of the expenditure.

(c) **CHEMICAL PRECIPITATION.**—In all those situations where neither of the foregoing methods can be used, or where so high a standard of purification is not essential—such as, for instance, discharge of the effluent into a tidal river, or a stream of such a size that, compared with the volume of the effluent, contamination is reduced to a minimum—chemical treatment can be most advantageously used. We have

likewise seen that where a high standard of purity is desirable the process offering the best hopes of success is that of chemical precipitation succeeded by intermittent downward filtration through a small area of land. It has been over and over again raised as an objection to chemical precipitation that, no matter what special reagent is used, the ultimate difficulty is the same, namely, the disposal of the large accumulations of sludge. In a paper read before the Institution of Civil Engineers by Mr. C. Norman Bazalgette,\* the author stated, as objection to chemical precipitation, that "it is impossible to manipulate the enormous accumulations of sludge necessarily incident to treatment by chemicals," and further, that when chemical treatment preceded natural filtration, "the accumulation of sludge is an objection inseparable from their use," *i.e.*, chemicals. It has, however, been before shown that irrespective of the method of purification pursued, the same ultimate difficulty results, *viz.*, the formation and accumulation of sludge. So that, instead of the evil resulting from chemical processes as such, the sludge difficulty is one inseparable from efficient modes of sewage disposal. Such being the case, the importance of an economical and efficient mode of dealing with the sludge can hardly be overestimated, because, to quote the words of Mr. Shelford,\* "information obtained showed distinctly that the sewage question resolved itself into the difficulty of disposing of the solid matters in suspension."

#### DISPOSAL OF SLUDGE.

Sewage sludge proper, as left after precipitation, is a thin mud, containing from 90 to 95 per cent. of water, the remaining part consisting of the solid matter, organic and mineral, originally suspended in the sewage, a small amount of the soluble organic matter precipitated by the chemical reagents, and more or less of the reagents themselves used for defecation. The large quantity of water it contains renders it exceedingly bulky, and this, together with its offensive character, constitutes the chief difficulty of its treatment. Unless deprived of the greater portion of its moisture, however precipitated or obtained from the sewage, it enters in putrefactive fermentation of a more or less violent and offensive nature. As obtained from the various chemical processes, it is yielded in quantity equivalent to from 1 to 1.25 ton for every thousand inhabitants contributing to the sewage; but this, together with its character, depends upon the nature of the district, whether manufacturing or rural, the time of year, the mode in which it is obtained, and a variety of other circumstances. No material, perhaps, varies more in its character than sewage sludge, unless it be the sewage from which it is collected. Many attempts have been made to reduce it to a condition in which it can be handled and got rid of, the majority of which have directly had for their object the recovery of the small amount of manurial matter it contains. How little success or economy these various appliances have attained is attested by the almost universal resort had to the mode of dealing with the sludge up to very recently. This mode, primitive enough in its simplicity, consists in draining the accumulations of deposit into large pits, several feet deep, where it is allowed to remain until it has parted with a sufficient amount of moisture to allow it to be dug and carted away from employment as manure. Even after being thus exposed for a period of as much as two years, evaporation and soakage have removed only a comparatively small amount of its water. In the meantime, the offensive odours given off pollute

\* "Methods of Disposing of Sewage Adopted in Various Towns in England" (Report to the Town Council and Board of Police, Glasgow, 1878).

\* "Minutes of Proceedings of Civil Engineers," vol. xlviii.

the atmosphere of the whole neighbourhood, experience of which no doubt originated the remark quoted by Messrs. Rawlinson and Read,\* "that the nuisance chargeable to such works is due not to the act of precipitation but to the process employed for drying the solid matter." We may briefly summarise the methods attempted under two heads—(a) Evaporative methods. (b) Mechanical methods.

(a) **EVAPORATIVE METHODS.**—All such processes as depend upon the application of artificial heat cannot attain any degree of success, (1) on account of the expense they entail both for fuel and labour, (2) the pollution of the neighbourhood of the works by offensive odours inevitably given off. The removal of the water by evaporation, as will be apparent, is infinitely more complex than the simple evaporation of water in an ordinary boiler, in which, under ordinary circumstances, good fuel will evaporate from 7 to 9 times its own weight of water. So high an evaporative efficiency is impossible with sludge, and it is more than probable that not more than one-third such effect has ever been attained. Upon this basis of calculation the following shows the quantity of fuel required for reducing the sludge to a condition in which it can be easily handled, containing 50 per cent. of water. One ton of wet sludge contains—

Solid matter (40%) = 2 cwt.  
Water matter (60%) = 18 cwt.

A sludge yielded by drying down to 50 per cent. moisture contains—

Solid matter = 2 cwt.  
Water matter = 2 cwt.  
Water evaporated = 16 cwt.  
Coal required to evaporate 16 cwt. of water at efficiency given above } = 6 cwt. (about)

The cost for labour and maintenance is proportionately high likewise. The cost of drying by Milburn's machine, at one time in use in several sewage works, has been stated to be in one instance £1 per ton, and in another £1 8s. 9d. per ton. Such expenditure cannot, with a material of so little value, offer any hopes of success, and, accordingly, we find that machines of the evaporative type have been altogether abandoned.

(b) **MECHANICAL METHODS.**—Under this head we may perhaps first notice the method of disposing of the wet sludge by pumping it direct from the tanks on to land, into which, after air-drying, it is dug. At Birmingham the sludge produced by lime treatment, amounting to upwards of 350 tons per day, is got rid of in this way, and it was originally thought that it would so quickly rot away that within two years the same land could be used over again. Such, however, is not the case. In 1877 Mr. J. Mansergh, C.E., stated, "Such a process as that of digging in the immense quantity of sludge produced by the lime process at Birmingham was unlikely to be of long duration;" and his remarks have been fully borne out. Ninety acres of land are annually required for this purpose, and if continued much longer it cannot be denied the whole area must ultimately become a mass of sewage filth. In 1876 the cost of removing from the tanks and digging in 109,500 tons of sludge is returned as £12,778, equal to about 2s. 4d. per ton. Mr. Ed. Monson has proposed to deal with the sludge by making it into bricks, the manufacture so carried out effecting a return for the expenditure upon the purification. This plan seems to have been tried in one or two cases—for instance, Leicester and Birmingham—but from reasons sufficiently obvious I am not aware that it has ever been adopted. Brick-making, as already pursued, is an industry far from

being agreeable. What it would become when in addition there would be added those infinitely worse odours of first baking, and then slowly burning the organic matters contained in the sludge-made bricks, can perhaps be better imagined than described. The brick shown was made by this process from the sludge accumulated at Leicester, where there is sufficient bulk of old deposit alone to test the efficacy of the process for some years to come. Many other similar proposals for mechanically dealing with the sludge have at different times been made, amongst the most successful being the late General Scott's cement process; but as in each instance the bulk of the water must be eliminated before their object can be attained, consideration of them is beyond our present purpose. Separation of the liquid and solid matter has frequently been attempted by the use of centrifugal machines; but however admirably adapted to the expulsion of a mother-liquor from a crystalline magma, where the force of separation to be exerted is comparatively small, and the proportion between the solid and liquid fairly even, little effect is obtained by their use in materials of the same slimy character as sewage mud. Wicksteed patented their application to this purpose in 1851, and up to 1870 they appear to have been occasionally used. Not more than one-half of the water can be removed by them, and the residue, consequently, is not in a condition in which it can be easily handled, nor is its offensive character much modified. Such a result, which even then is only obtained by considerable expense, quite justifies the remark made in 1870 by Dr. Odling, when asked his opinion of the process: "It seemed to me to be perfectly inefficient." Of all modern industrial appliances for the separation of liquid from solid matter the class of apparatus known as filter presses offers the most practical advantages, being capable of such modifications as admit of their successful application to an infinite variety of purposes. As manufacturers of such apparatus the firm of which I am a member (S. H. Johnson and Company, of Stratford), with a knowledge of the many unsuccessful attempts made in the directions indicated in the foregoing part of this paper, as well as the ineffectual attempts to adapt the filter press also to the same purpose, began some five or six years since to turn their attention to the production of suitable and efficient machines. As may be imagined, such a system was not easily elaborated; but after some three or four years' attention to the many details necessary to be worked out practically the whole of the difficulties have disappeared, and we are now able to place before you machinery which for a considerable period has been satisfying the conditions of the problem we have been considering, and to a description of which we shall now pass. A filter press consists of a number of narrow cells held in a suitable frame, the interior faces being provided with appropriate drainage surfaces communicating with an outlet, and covered by a filtering medium, generally cloth or paper. The interior of the cells so built up are in communication directly with each other, or with a common channel for the introduction of the matter operated upon; and as nothing introduced into the cells can find an exit without passing through the cloth the solid matter fills up their interior, the liquid leaving by the drainage surfaces. The cells of the machine being subjected to an hydraulic pressure, which increases as the operation goes on, and as the growing resistance offered by the increasing thickness of solid matter on the cloth, must of necessity, on their exterior touching surfaces, be mechanically made true and pressed together with force sufficient to prevent the material operated on escaping. The force exerted upon the material

\* "Modes of Treating Town Sewage," 1876.

driven into the press, whether by a pump or other means, must be considerable; and as both sides of a cell are subjected to the same pressure in opposite directions, it follows that if nothing, such as a local stoppage, interferes with this equality of pressure, the diaphragms are in equilibrium as regards pressure. To be of any utility, in dealing with daily accumulations of sludge, the machines must be of considerable size, because, even for a population of 30,000, about 30 tons have to be dealt with during the day. Difficulty of making large plates sufficiently rigid and tight at once appears, but as far as this is concerned it has been met by adopting a circular shape, a form which above all others for strength and resistance to the internal fluid pressure is at once apparent to the mechanical

equilibrium of opposite pressures on each side of the adjacent cells is destroyed, and the plates, even under moderate pressure, unless made of a thickness quite impracticable, collapse and break, a result which the usual size of the machines, 3ft. and upwards in diameter, readily encourages. For example, at Coventry the employment of two such presses, each with 24 plates, led to the destruction of no less than upwards of 60 plates in a few weeks from no other cause. The remedy for this is as efficient as it appears simple. Instead of the central parts of the cells being kept entirely apart, suitably-shaped projections are formed on their surfaces, which are faced down to the same plane as the exterior joints, so that when the machine is

Fig 3

mind. It would be impossible to enter into all the minor details of construction which experience has proved to be necessary to success, but although not here noticed they are none the less important, as each in its particular manner contributes to the result. Only the leading and most vital features will therefore be dwelt upon. The most disastrous difficulty we have had to contend with has been the stoppage of the feed passages, due to the heterogeneous character of the rubbish and fibrous matter present, which only too easily builds itself up, whenever the least excuse offers, into hard blocks. The inevitable consequence of the stoppage of any of the chambers is that the

screwed up these nip the cloths between them, and bearing upon each other form a series of stays from one end of the machine to the other, supporting the plates when the equilibrated pressure is destroyed, until the higher pressure forces the obstruction away. Since the introduction of this simple device no fracture has occurred in any machines to which they have been applied, and experience enables us to state positively that without such a method of support no filter press can be successfully used for sewage purposes. This plan will be clearly understood from the woodcut (Fig. 1), showing a front view and section of large sewage filtering plates. Another requirement equally important is the mode of in-

troducing the sludge into the press. In most cases of filtration an hydraulic pump is used, and where the matter is not too thick, and contains *little or no fibrous matter*, answers sufficiently well with small quantities. But we speedily found that with the mass of fibrous matter and rubbish with which we had to deal the valves of the pumps continually became choked, and operations were inevitably interrupted at the most vital period. The large quantity of gritty silicious matter, as would be expected, rapidly cut the working parts to pieces. The plan has therefore been followed of running the sludge, or drawing it by *vacuo*, into cylinders placed underneath the presses, and large enough to contain a charge. From this vessel it is forced by compressed

speed of the compressor can be kept constant and the power stored up, ready to be drawn upon when required. Again, pumps must not be worked for such a purpose above about 40 strokes per minute: consequently the rate of feed at the commencement of the pressing is too slow. An efficient air compressor can be constructed to run at 100 strokes per minute, and therefore, irrespective of air accumulated, the press can be fed rapidly, economy of time being the result. Other important advantages could be enumerated. The addition of a small quantity of fresh lime just before pressing considerably adds to the facility of the operation. The results of the operation, briefly described, are—within one hour every five tons of wet sludge containing 90 per cent.

NUMBER II.  
PERIODS OF TIME—HOURS.

Fig 4

air, of a pressure of 100lb. to 120lb. per square inch, into the press, the air being supplied by a suitable compressor, pumping in the case of two or more presses into a storage vessel. The press is thus instantaneously filled, filtration commenced immediately, and the whole operation is completed in about one hour. The advantages of the compressed air system are many besides that which has been shown. It is found to be more economical than by employing pumps if the quantity of material to be operated upon is large. It is of course evident that as the filter press operation approaches completion less material is required. With a pump this would escape through the relief valve, and the power be lost; with compressed air, working on an elastic medium, the

of water can be deprived of 88 per cent. of its water, giving a residue of one ton of hard-pressed cake, containing 45 to 50 per cent. of water. The cake so obtained is easily handled, is practically inodorous, air dries very rapidly, and does not again enter into fermentation. It can be kept for any length of time without smell or nuisance. In this condition it can be disposed of in the immediate neighbourhood as manure, for which purpose, as will be noticed, it is available. How far further expenditure, having fulfilled the sanitary requirements of the problem, is justifiable upon a material of so little value can be judged of from the records of past experience; but whatever its ultimate destination, there can be little doubt that the condition in which it leaves the filter

press is that in which it can be most cheaply dealt with, whether for purposes of utilisation or destruction. The woodcut (Fig. 2) shows the arrangement of plant for dealing with the sludge from a population of 30,000, comprising the following apparatus: Air compressor; air accumulator; two sludge filter presses, 3ft. diameter; two sludge forcing vessels, with their fittings and the various distributing pipes for sludge and air; a tip truck and tramway for the removal of the pressed cake discharged from the machines. The cost of such a plant with the requisite boiler power (about 10 h.p. actual) is about £1,000. Thirty tons of wet sludge can be easily pressed into cakes, containing 50 per cent. of moisture, equalling six tons, or one-fifth of the original bulk, consisting of five charges from each machine, of 12 cwt. each, in ten hours. The labour required is about two-thirds of the time of two men. The cost of the operation determined from actual work, extending over two years at Coventry, amounts, with all expenses included, to sixpence per ton of wet sludge, or half-a-crown per ton of pressed cake, and on a larger scale this expense will be somewhat less. The following works may be quoted at which this method is pursued, and where, in some cases, operations have been going on for upwards of two years:—

Croydon Rural Sanitary Authority)	Baldwin Latham,
High Wycombe .....	Esq., C.E.
Coventry .....	The Rivers Puri-
Leyton .....	fication Assoc.
Blackburn .....	General Scott's
	Ammoniacal
	Filmus Process.
Aylesbury .....	Native Guano Co.

It may also be added that Messrs. Mansergh and Melliss have recommended its adoption in their lately published report to the Lower Thames Valley Main Drainage Board.

#### SEWAGE SLUDGE AS MANURE.

The idea of converting sewage residues into manure yielding a profit upon the whole operations of sewage treatment, has for some years been rightly viewed as fallacious, and allusion need hardly be made to the failure of the many plans tried with this object. There is, however, no reason why sewage sludge, when deprived of its water, should not be so used, and although too poor to pay the expenses of carriage to a distance, when filter-pressed, it can be profitably employed by the farmers in the immediate neighbourhood. At Coventry this has proved to be the case, for whereas the partially air-dried sludge had either to be given away or got rid of at a charge to the works, the filter-pressed sludge is purchased by the farmers at 3s. 6d. per ton and upwards. It is, however, by no means put forward that this should be the object of so treating the sludge—that must ever remain a sanitary necessity—but as occasion offers it is evident a reduction of the working expenses can by this means be effected, especially if a little care be exercised in handling it after it leaves the filter press. Air-dried it parts with its moisture readily, and the amount of water can thus easily be reduced to 20 per cent., in which state it can, if desired, be easily ground. Being so deficient in those elements which constitute the value of a manure, it cannot of course be taken upon the same basis as artificial manures. There is, however, no doubt that it is fully equal to, and in some cases more valuable, according to analysis, than farmyard manure. Having regard to the fact that the usual price of the latter

never exceeds one-half its analytical value, sewage sludge, with which it fairly compares, should be valued on the same basis. The following examples are selected from results given by the sludge from different systems of treatment, taking into consideration the nitrogenous matter and phosphates only. Nitrogen, calculated to ammonia is taken at 6s. per unit. Phosphoric acid calculated to neutral phosphate of lime at 6d. per unit. The resulting values are shown both for cake containing 50 per cent. moisture as coming from the filter press and also cake air-dried down to 20 per cent. moisture:—

Sludge from Treatment of	Pressed Cake, 50% Water.			Air-dried Cake, 20% Water.		
	Ammonia.	Phosphate of Lime.	Value per Ton.	Ammonia.	Phosphate of Lime.	Value per Ton.
			s. d.			s. d.
Sulphate of Alumina and Lime .....	0.81	1.81	6 0	1.36	2.9	9 7
Lime .....	0.5	2.06	1 0	0.80	3.3	6 5
A B C Process .....	0.69	0.65	1 6	1.10	1.01	7 2
Hansons' Process; Alkali Waste and Lime .....	0.5	0.98	3 6	0.80	1.57	5 7
M. and C. Process; Lime, Carbon, Soda, and Perchloride of Iron .....	0.62	0.86	1 2	1.00	1.37	6 8
Paris Sludge from Liep-nur's System treated with Sulphate of Alumina .....	2.20	7.5	17 0	3.52	12.00	27 2
Manure made from Pail Emptyings, Goux System .....	0.82	0.96	5 6	1.31	1.57	8 9

From the above analyses it will be seen that the value of the pressed sludge is fully equal to that of farmyard manure; and this statement is borne out practically by the statements of Lieut.-Col. Jones, V.C. "He had tried sewage sludge side by side with farmyard manure, and with 60 per cent. of moisture it was, bulk for bulk, rather superior to the manure."

Before leaving this part of the subject, attention may be directed to the result shown by the manure made from pail emptyings; and it will be seen that even after the expense of separate collection is incurred, the result is of no more value than ordinary sludge, fully establishing from this, as well as from a sanitary point of view, the inefficiency of such processes. The high value of the pressed sludge from the Liermur system of collection is easily understood. Collected by an elaborate pneumatic system, all else save excreta and urine is excluded, and after treatment with a small quantity of sulphate of alumina it forms, when pressed up into cakes by the filter press, a manure far richer than any sludge from water-carried sewage.

#### INFLUENCE OF PRECIPITANTS UPON THE SLUDGE.

A variety of reagents have been used by different inventors for the effectual defecation of sewage, the object in view being the precipitation of the suspended matter and the coagulation of the slimy organic bodies present in solution, as well as in some instances the utilisation of the valuable constituents, five-sixths of which are in solution and pass away in the effluent. Those commonly in use are lime or salts of lime, sulphate of alumina, clay, and salts of iron—and these

are used in a variety of ways, either alone or in conjunction with each other. Phosphates of alumina and lime have also occasionally been used, but their cost, viewed in relation with the inadequacy of the value of the resulting product, of course prohibits their use.

The requirements of a precipitant, as far as regards its effect upon the sludge, are threefold: (1) Rapidity of subsidence of the precipitate formed; (2) the production of a precipitate of minimum bulk with maximum defecation; (3) the sludge obtained should part with its water readily.

In order to determine the most suitable reagent for this purpose consistent with cost, we carried out a series of experiments some time ago, some of the results of which are graphically shown by the curves in Figs. 3 and 4. The substances used were lime, sulphate of alumina, and salts of iron, alone and in different amounts, as well as in conjunction with each other. To determine the effect of these upon subsidence, a standard solution of concentrated sewage was made, containing 20 per cent. of the Paris sludge previously referred to. Measured quantities of this solution were placed in wide tubes all of the same size and depth; the rates of subsidence for different quantities of the reagents were noted and the results expressed by the curves shown in diagram No. 1, Fig. 3. To determine the readiness with which the different precipitates so formed would part with their water during filtration, the contents of the tubes after complete subsidence were agitated and thrown on to filters of the same size and shape. The filtrates were received into graduated measuring tubes, the quantities passing through the filters in a given time being accurately noted, and the results so obtained expressed by the curves shown in diagram No. 2, Fig. 4. The following particulars refer to both tables of curves, the percentages of the reagents being expressed upon the thick sludge originally taken:—

Curve.	Reagent used.	Quantity used.
C <sub>1</sub>	Lime	1/2
C <sub>2</sub>	Lime	5
A <sub>1</sub>	Sulphate of Alumina	1
A <sub>2</sub>	Sulphate of Alumina	5
(A and C) <sub>1</sub>	Sulphate of Alumina and Lime	1
(A and C) <sub>2</sub>	Sulphate of Alumina and Lime	5
Fe	Ferrie Chloride	1

Referring to Fig. 3, we learn the maximum amount and rate of subsidence within a given time is that due to the addition of equivalent proportions of sulphate of alumina and lime, and that the precipitate produced by chloride of iron is almost as rapid and the precipitate is less bulky. Referring to Fig. 4, we find that lime-treated sludge parts with its water with no more facility than the untreated sludge. That the sludge from sewage fully precipitated by sulphate of alumina, or equivalent proportions of sulphate of alumina and lime, parts with its water the most readily. An interesting point as to the action of lime is clearly shown in Fig. 4: the coincidence of the curves A<sub>1</sub> and (A and C)<sub>1</sub>, A<sub>2</sub> and (A and C)<sub>2</sub>, points to the conclusion that the lime has little effect upon the filtration, its action being explained by Fig. 3, viz., as a weighty body assisting the rapid subsidence of the sludge.

#### CONCLUSIONS.

The following are the conclusions submitted as a result of the present paper: (1) Every effectual system of sewage disposal is accompanied by accumulations of sludge. (2) That of all the systems employed for the disposal of the sludge, that by means of properly-constructed filter presses offers the most advantages. (3) That pressing the sludge enables it to be disposed of as a weak manure, and that it is at

least equal in value to farmyard manure. (4) That precipitation by sulphate of alumina and milk of lime seems to be the best method of obtaining a rapid subsidence, and a sludge most easily filtered.

#### DISCUSSION.

The CHAIRMAN said he had no doubt they had all listened with great interest to this paper, which put forward most clearly and graphically the most recent progress in this very difficult investigation. Those who had paid attention to the subject would appreciate the truth of the statement that the only thing to be done with sewage was to treat it with some precipitate before putting it on stand, without which the sewage irrigation became an abominable process, and nearly everyone had been met with the almost hopeless difficulty of dealing with the sludge. The paper was also interesting in showing the exceedingly skilful manner in which the special difficulties of filtering a most inconvenient body could be overcome. Of course, every fresh substance needing filtration required somewhat different treatment, and special forms had been devised for special purposes. He should be glad to hear the experience of those who had had to deal with sewage sludge. Whether London would ever set up a sufficient number of presses to dispose of the vast quantity of the metropolitan sewage he did not know. It must be remembered that they had not only to deal with the sewage below London Bridge but that above. This was a matter of vital importance, and could only, in his opinion, be dealt with by the system which had now been advocated, for from all he had been able to hear, he did not think there was any more efficient system of filtration than that now described, and he could speak from considerable practical experience.

Major FLOWER said as the chairman had referred to the pollution of the river Lee at Luton, he was happy to say that the suspended matters in the sewage of Luton were precipitated by lime and clay, and the effluent was afterwards passed through a sufficient area of land; therefore, they might drink the water with perfect impunity. He really thought the proposed mode of getting rid of sewage sludge was most valuable, having seen a great deal of it, for he had spent the last thirteen years of his life entirely on this very filthy subject. The disposal of the sewage sludge was, in fact, the very head and front of the difficulty in treating sewage. At the beginning of the paper Mr. Hutchinson had drawn attention to the different modes of disposing of sewage. It might be somewhat egotistical in him, but he was proud to say he was the first man who advocated the chemical treatment of sewage, and afterwards its utilisation on land. That system was first carried out at Enfield, because the irrigation farm, which was on low-lying land, became such an abominable nuisance. The Enfield people had unfortunately, contrary to his advice, taken to irrigation again, for the company which undertook to treat their sewage by Whitbread's dicalcic phosphate process had broken up, and they again found how horribly deficient irrigation alone was, especially when, as at Enfield, the sewage was poured into a water-logged stratum. There the water-table of the country was only 4ft. below the surface. At Tottenham they employed a method which was very fair in its way, but the sludge was a most abominable difficulty, and he believed the very excellent system of filter-pressing sludge was about to be brought into use there. He saw this press in its early days at West Ham, had watched it thoroughly in its progress, and was pleased to find it had arrived at such a point that he thought engineers might really, without stretching their consciences, recommend its adoption on a very large scale.

Mr. DOUGLAS A. ONSLOW had great pleasure in testifying to the efficiency of S. H. Johnson and Company's presses. He had been connected with defecation of sewage by means of precipitation at Coventry for the last seven years. When they first commenced work there they attempted to get rid of the moisture contained in the sludge by means of Milburn's drying apparatus, but the cost of doing so was so extravagant that they were compelled to abandon it, and for want of anything better they ran it into large open tanks, and allowed it to dry as rapidly as it could be evaporated by the air. This was an extremely inefficient way of doing it, and was objectionable in every sense. They made several efforts in a small way with filter presses before meeting with S. H. Johnson and Company, using a somewhat similar form of press, in which, instead of compressed air, they used pumps, but the objections proved very great, and it was found impossible, at any reasonable cost, to get satisfactory results. Fortunately they then came into communication with Messrs. S. H. Johnson and Company, and since their presses had been put up the only difficulty they had had was the breaking of the diaphragms which had been alluded to in the paper, and that was remedied in the way described. This having been accomplished, the pressing had now attained such a degree of efficiency that they had been able to press in the course of one week, working night and day, no less than 476 tons of wet sludge. The necessity for that arose because the presses were insufficient to deal with the total quantity made daily, in an ordinary day's work, which thus caused an accumulation rendering it necessary at times to work night and day. Were it not for that, it would be almost impossible to carry on the operations which, as he contended, had been successfully carried on for the last seven years at Coventry. At any rate, they had been able to deal with the sewage of the whole population of Coventry, 45,000 to 46,000, with the assistance of an area of eight acres of land for the filtration of the effluent water. He was satisfied that the only possible way of dealing with this question was by means of chemical precipitation first, and wherever possible afterwards the filtration of the effluent through land. There were many instances where it was impossible to get land even of sufficient quantity to filter the effluent water from the tanks, and therefore it became necessary to know what was the best possible precipitant to be used for the purpose of getting such an effluent as might be discharged with the least possible harm into the river or ordinary water channels. The paper had dealt most admirably with the details of the presses, and after 2½ years' experience at Coventry they were thoroughly satisfied with them. Mr. Hutchinson had said that they got 3s. 6d. a ton and upwards for the compressed sludge, but as he did not wish anyone to be misled on that point, he ought to say that they got from 2s. to 2s. 6d., but the farmers sent from eight to ten or twelve miles to fetch it. He did not think it was possible to hope ever to realise anything profitable in the shape of returns for the sludge, the manurial value being too small; but still, even if the returns were small, it was something to be able to get rid of that which until lately had been an incubus, which, when it came to many thousands of tons per annum, became a source of great anxiety.

Dr. C. R. A. WRIGHT asked what was the proportion between the amount of nitrogen contained in a given quantity of the original sewage which was carried away by the effluent and the amount retained in the sludge, and the same with regard to the phosphoric acid.

Mr. T. W. B. MUMFORD said the question had

occurred to him that it was all very well to talk about the disposal of sludge and running off a clear effluent afterwards, but he could not understand how large centres were going to be dealt with, where the population was very large, and the district was subject to heavy rainfalls. How would it be possible to get the whole of the rain-water accumulated over a large area dealt with in this way? This appeared to him to be a weak point in the process. There would be at times enormous quantities of water coming down the drains and mixing with the sewage, which would have to go somewhere, and therefore, however perfect the process might be for dealing with a certain amount of sewage, and with a certain area, there would be times when it would be impossible so to deal with it effectually.

Mr. CRESSWELL, in answer to the last speaker, said that most engineers were now agreed that a separate system of sewers was absolutely necessary, no rainfall being allowed to enter them. Major Flower had said that at Enfield they had used chemical precipitation followed by treatment through land. It seemed to him that such a system was unlikely to destroy the noxious qualities of sewage, because nitrifying germs were readily affected by chemicals, more especially antiseptics.

Major FLOWER asked if it did not come to this, that chemical treatment, after all, was simply mechanical, leaving the land to deal with all the putrescible organic matter in the effluent. He knew Colonel Jones's farm very well, and his practice was to leave the sewage for a very long time in his tanks, which were of a special construction, and there get rid by deposition of the matters in suspension, just in the same way as, on a larger scale, it had to be done by chemical means. It appeared to him that chemical treatment, after all, was only mechanical in its operation.

Mr. CRESSWELL said that Colonel Jones, V.C., told him emphatically that it was advantageous to treat sewage by subsidence simply, without addition of chemicals, and then to run the effluent on to suitable land, in which state it could be readily attacked by the germs.

The CHAIRMAN, in proposing a vote of thanks to Mr. Hutchinson, said it must be borne in mind that at best sewage precipitation was only a palliative, the land itself must take what remained in solution; but those who had seen the working of a sewage farm would know the ineffable abomination of applying unfiltered sewage to land in large quantities. Sewage precipitation never could carry down all the phosphoric acid, still less all the nitrogen; but it rendered it possible for the land to deal with the effluent afterwards, if land could be had.

Mr. CRESSWELL wished to explain that the question was as to the chemical action of land. It did not act simply as a mechanical filter, but as an agent for the oxidation into nitrates of the nitrogen of sewage; and the point he wished to emphasise was that the liquor must not be put on the land in such a state as to preclude the action of the germs.

#### REPLY.

Mr. HUTCHINSON, in reply, said, with reference to what the chairman had said of the overwhelming quantity of sludge which would be accumulated from the sewage of the metropolitan area, he thought, in the course of a few years, steps would be taken to carry out what he had stated as desirable in the paper, viz., the removal of the solid matter, admitting only the purified effluent into the river. The engineering difficulties could easily be got over, and were not by any means overwhelming. His firm would not have the slightest hesitation in entering into a contract to press up the whole of the sewage sludge of London every 24 hours, and he should feel

the utmost confidence in their power of being able to so deal with it. With reference to Major Flower's observation respecting the sludge nuisance at Tottenham, he thought probably if he went there in a few months' time he would not have the same complaints to make, as he hoped before then the sludge would be reduced to the inodorous condition as the specimens he had shown. Mr. Onslow had made one remark which he should not like to go forth without some little qualification. He said the reason they had to work their machinery night and day was that the presses were not able to deal with the whole of the sludge accumulated daily. Now he wished it to be distinctly understood that this did not arise from any fault of the presses themselves, but on account of the inadequacy of the size of the plant compared with the quantity of sludge they had to deal with. That plant was put up for dealing with about 28 tons a day, and, as Mr. Onslow had pointed out, they had actually pressed up 480 tons in one week, which was equal to 80 tons a day, working 24 hours, or 40 tons working 12 hours, clearly showing that the presses did 33 per cent. more work than they were originally intended to do. With reference to the error which he had pointed out as to the price obtained for the pressed sludge, he would say that perhaps they did not get what they should for it. It such cases much depended not on the actual value of the material, but on the idea you could give people of its value, and probably, if a little pains were taken, after the sludge came from the presses, to give purchasers an idea of its value, they might be able to get a few shillings more per ton for it. He suggested that a little care should be taken. It should not be thrown into a heap, and the farmers be told that they could have as much of it as they liked at 2s. per ton; but it should be removed in pieces from the presses, carefully handled, and suitably stacked under cover for air-drying. Such a course would considerably add to its value. The manager of the Coventry works had recently told him they had just entered into a contract for 1,000 tons at 3s. 6d. per ton. With reference to Mr. Mumford's observations, the process now brought forward did not pretend to enter into every phase of the difficulties connected with dealing with sewage, but simply the difficulty of dealing with the sludge. No matter what the rainfall was, whether it were 1in. or 40in., there would be a certain quantity of sludge to deal with, and the reply Mr. Cresswell had given to that question was perfectly correct. The conditions of modern sewage disposal decidedly pointed to the direction of keeping the whole of the solid matter and excreta entirely separate from the surface drainage and rainfall, because in dealing with a less bulky and dilute material it rendered the process of purification and disposal much simpler and less costly. In all those towns which were not yet fully sewered a separate system of surface drainage would be carried out for taking off the whole of the rainfall, which would pass into the watercourses sufficiently pure without any treatment. In those towns which already had a complete system of sewerage the plan was being adopted of providing storm overflows, the sewers being so constructed that when a certain quantity of water had accumulated in them, the remaining part due to the storm, which would be comparatively clean water, flowed over without any treatment into some stream. Mr. Cresswell said that Colonel Jones informed him that it was quite possible to deposit the whole of the solid matters in sewage by subsidence alone, but he would simply refer Mr. Cresswell to the observation of a philosopher in olden times, who demonstrated the possibility of moving the world if

he only had a lever long enough and a fulcrum on which to place it. The case of the simple subsidence of the whole of the solid matters in sewage without chemical treatment was somewhat analogous. Given sufficient tank area, and an unlimited length of time for the sewage to pass through those tanks, it would probably be possible for the whole of the solid matter to be separated by subsidence. In Fig. 3 the curve of subsidence of untreated sewage was shown to be practically a straight line, and it was coincident with the datum line. It was known by experience to sanitary engineers that it was practically impossible to settle out the whole of the putrescent matter in the sewage without chemical treatment. In reply to Dr. Wright, he believed about five-sixths of the nitrogenous matter passed away in the effluent, and that only one-sixth was precipitated in the form of sludge. The nitrogenous matter so precipitated was of the most objectionable character—namely, that present in the shape of albumenoids, which would most readily enter into putrefaction. That which went away in the effluent was principally ammonia salts, ammonia, and nitrates. The amount of phosphoric acid precipitated depended altogether upon the treatment pursued, the chief difficulty being the very dilute form in which it was present in the sewage. It was, however, quite manifest that such a treatment as that of sulphate of alumina and lime would throw down the greater part of the soluble phosphates as the insoluble phosphates of lime and alumina, and such a result was given in actual practice.

## THE PORTER-CLARK PROCESS.

BY J. H. PORTER.

THERE are few industries independent of the character of water supply, whether as regards the production of steam or the excellence of the results of various operations, technical and artistic. In both the presence of the carbonates of lime, magnesia, and iron in the waters employed is a continual source of loss, often very great, as in the incrustation of boilers, which is inadequately appreciated. Dr. Clark's water-softening process has necessarily but limited application, in consequence of the large space required on the one hand for mixing and settling tanks, and on the other, the time required for the subsidence of the precipitated carbonates. The desirability of applying the process, chemically perfect as it was, suggested the idea of filtration for the removal of the suspended carbonates. Many patents were taken out for devices for effecting this object, and so far the most successful one has been that known by the title of this paper. In 1877 Sir Frederiek Bramwell read a paper before the British Association on the subject, and Mr. James Duncan was the first to practically test the process on a large manufacturing scale at his sugar refinery. Other refiners have followed suit, as also some railway companies, as the London and North-Western Railway at Camden, Willesden, and Liverpool; paper makers, dyers, brewers, and others. At first open tanks for continuous softening and filter presses for continuous filtration were used, as at the Silvertown Indian Rubber Works. For greater economy of space, and essentially to avoid the necessary second pumping, was devised the method of working under pressure, by which, indeed, pumping is altogether avoided when working under gravitation.

Figs. 1 and 2 represent the plant in use at the locomotive sheds of the London and North-Western Railway at Camden, for treating 7,000 gallons per hour continuously, and where water of 17° to 18°

hardness is reduced to 4°. The water treated at Willesden and Camden is pumped from deep wells in the chalk near Watford, and reaches those stations by gravitation, and with a pressure of 60lb. to the inch. Except when treating very small quantities of water, continuous agitation is maintained within the vessel of the apparatus. This pressure is utilised in working a Ramsbottom water engine or motor, which Mr. Webb (head of the locomotive department at Crewe) suggested for the purpose. The exhaust water from the motor is conducted (still under

agitation, and passes out and upwards to the tallest vessel, in which saturation of water with lime takes place. The particles are prevented from settling out by the slowly-revolving agitator. The saturated and almost clear water passes from the upper part of this vessel (which has a sampling cock at due elevation) to the dome on the shorter vertical vessel, by a pipe, fitted with a regulating valve. Hard water from the main is also entered here, working the motor on its way. The two streams thus mix in this dome at about equal pressures, and decomposition is effected

FIG. 1.

pressure) into and through the system of vessels and filters. Leaving the separated and suspended carbonate of lime in the latter, it passes up to the elevated service tank. The diagram exhibits two large vessels 7ft. in diameter, and respectively 13ft. and 17ft. in height. In addition is a horizontal cylinder or churn, 2½ft. diameter by 4ft. long. All three vessels are fitted with agitators, driven by shafting worked by the Ramsbottom motor, but so geared as to give to the agitator in the tallest vessel a speed of about ⅓th of the other two. In the churn, slacked lime is kept

completely and rapidly. The suspension of the separated particles of carbonates is continued through the shorter vessel to the connected filter presses, in which they are arrested. (A frame containing separated carbonates of "great whiteness from the Camden plant was exhibited.)

In the case of certain waters containing much organic or aluminous matter, the older direct method of Dr. Clark was useless. The improved process is successfully applied to water drawn directly from the Thames. In such cases it is necessary to employ pure water

(as from the companies) or previously treated water for the production of lime water. This consideration has not affected the economical use of the improved process. (A frame containing carbonates and suspended matters of a dark umber colour was exhibited.) It is scarcely necessary to add that any intelligent workman soon becomes *au fait* with the tests indicating the due proportions of the hard and lime waters during the softening process. Nor is it needful to indicate the possible adaptations of the process in a meeting of this Society. But one at any rate may be referred to, viz., the prevention of "incrustation" in boilers, a subject which has been ably treated in the Section by Mr. Ivison Macadam. To large steam users this has an estimable value in the prevention of frequent stoppages for chipping out, for occasional repairs, and considerably in the saving of fuel. The engineer of the Manchester Steam Users' Association, in his report to the committee, points out the desirability of throwing out the impurities of feed waters before entering the boilers, and not in them. This gentleman expresses the hope that the Porter-Clark process might be made available for the removal of sulphates in some similar

disruption from the presence of confined gases. With regard, however, to brewing, it has been found that water deprived of its carbonate of lime more readily acquires "brewer's" hardness by solution of "sulphate" where artificial hardening has to be resorted to. The immense saving in numerous directions which would result from the use of an efficient system of softening water on a large scale needs no demonstration. We venture to think that we have gone some way to the fulfilment of this end by a process which is calculated to accomplish this effectually and economically; for in general terms it may be said in this as in many other cases the larger the scale of operation the smaller the cost. In specific terms one may say the space occupied is small, and the clarification immediate. Suffice it to say that in the following towns using the process the figures indicate the reduction in hardness:—

Canterbury .....	26.3 to 1.9
Caterham .....	21.2 to 1.1
Tring .....	26.3 to 3.2

#### DISCUSSION.

Mr. B. E. R. NEWLANDS said this process had been worked at Mr. Duncan's sugar refinery, Clyde Wharf

FIG. 2.

manner. With regard to this latter point there are considerations of cost, which are rapidly lessening in consequence of the cheaper production of certain apparently necessary chemical agents.

In one of the London works in which the process is now used, and 400 tons of fuel are disposed of weekly, 60 tons less were formerly burned immediately after periodical chipping out. Mr. Macadam, in his paper, states the loss of fuel as 30 per cent. Mr. Rowan gave 15 to 60 per cent. as the range of loss. At a paper mill, by an apparatus similar to that of the London and North-Western Railway Company, a saving was effected of 14 cwt. out of a consumption of 7½ tons daily under the old conditions. It may not be uninteresting to mention that occasionally the delicacy of the water-mark of the Bank of England note-paper was impaired by the presence of small granules of carbonate of lime, which became mechanically retained in the delicate wirework designs. This trouble is now obviated by the adoption of the Porter-Clark process. One need scarcely refer to the use of certain waters in breweries, but for the production of ice it has been found that the greater the freedom from carbonic acid the water employed can be the more transparent the ice and the less liable to

Victoria Docks, for several years. In fact, the first practical apparatus was erected there, and all that Mr. Porter said with regard to its successful operation had been fully borne out by actual results. With suitable water, such as that supplied by the East London Water Company, which was good compared to that obtained from the artesian well at Clyde Wharf, the hardness could be reduced to an extremely low limit. With Clyde Wharf water they were not quite so fortunate, because it contained a large quantity of alumina, magnesia, and organic matter, and these impurities prevented the removal of the hardness to some extent. Still there was doubtless a great improvement in the water after treatment. He saw on the table an old friend of his, namely, a piece of lead pipe which he gave to Mr. Porter a year or two ago, taken from a pipe leading to a condenser. This pipe was almost closed by incrustation. The cause of this was not quite certain, as a rapid current of water continually ran through it; but it may have been due to the precipitation of calcic carbonate, owing to the removal of carbonic dioxide by the vacuum. Every three or four months the pipe used to stop up, but since the Porter-Clark process had been employed no trouble had been experienced.

Great credit was due to Mr. Porter for the admirable way in which he had carried out his recent improvements. At Clyde Wharf they had his earliest form of automatic arrangement for regulating the amount of lime water, which answered very well, but the new apparatus, such as had been described, was no doubt a great advance in the right direction.

Mr. J. J. EASTICK said he could bear testimony to the benefit of the action of the Porter-Clark process upon water taken from the Thames between Blackwall and Woolwich. Unfortunately the composition of the Thames water fluctuated considerably, so that we had a slight difficulty with regard to the proportion of lime water to be added, but that was the fault of the water, not of the process. If the proportion of lime was too little there was great difficulty in filtering, but by so arranging the lime valve as to always have a slight excess this difficulty was removed, and no great objection was found to the presence of this lime in the boilers. Another advantage was in the use of the water while warm, which was found to render the filtration much more effectual. In making the lime water at Silvertown they used the water which had been treated, or else they used the East London Company's water; but they had used the Thames water direct, and found it to answer very well.

Mr. JOHNSON was also pleased to bear testimony to the efficiency of the working of Mr. Porter's apparatus, which he had seen on various occasions at different works. In one he had looked into, a tank of water was softened by this process, and he noticed that besides removing the carbonate of lime it rendered the water so clear that he could conceive that it would be possible almost to read a newspaper at the bottom, a depth of 24 ft.!! The water lost that peculiar yellow colour due to the organic matter of the ordinary water supplied by water companies, and had the blue of pure water; and he thought that ought to go a long way to recommend the adoption of this process by water companies. In the sixth report of the Commissioners on the pollution of rivers it was reported by Dr. Frankland that the treatment of water by Clark's process ought to be adopted, and that the companies ought to be compelled to use it before they were allowed to raise additional capital. Mr. Porter had not alluded to the various recommendations of the Commissioners in favour of soft water, such as the advantage in the making of tea, coffee, and cocoa. He believed that from one-half to two-thirds of the tea used in London could be saved by this means. There would also be an immense saving of soap in laundries, for it had been shown that a very small quantity of lime (one farthing's worth) was equal to a saving of about 30s. worth of soap. All these things went to show what great economy there would be by the use of soft water for household purposes. These matters might seem trivial, but when taken on a large scale they became important. He should like to know what would be the cost of this process on the waterworks scale. Mr. Porter had stated that it would cost about 1d. per 1,000 gallons on the scale of a quarter of a million gallons a day, which would come rather expensive on the scale of 10 or 12 million gallons. Dr. Frankland stated in his report that it could be softened for about £1 per million gallons, and he should like to hear if any calculations had been made on that point. It was also stated in the same report that the carbonate of lime precipitated had a certain commercial value, which might be taken as a set off. It was put down at 15s. per ton, and it was said that about three tons of carbonate of lime was produced for every ton of lime used in the process. If this were so it would more than pay the cost of the lime, but no doubt this would greatly

depend on the quality of water treated. Where the water came from deep wells in the chalk very little organic matter would be separated, and then the material ought to have a market value greater, he should think, than that of ordinary whitening. He had examined under the microscope the lime precipitated by this process, and comparing it with ordinary whitening he found that it was perfectly crystalline, whereas the latter was amorphous. Possibly this might have some effect on its commercial value. He would also ask Mr. Porter if he had adopted the silver test for testing the water for excess of lime after it had been subjected to this process, which he thought was more practicable for a workman than by boiling the water or using Dr. Clark's soap test.

Dr. MESSEL said: I have received some favourable reports from the Continent of a process in which magnesia is employed instead of lime as in Clark's process. By its means the lime, combined with sulphuric acid, is precipitated as well as the carbonate. Sulphate of magnesia is formed at the same time, and it has no injurious effect on the boiler. If burnt dolomite could be employed the process ought to be as cheap as it is said to be effective, and Mr. Porter's apparatus seems well adapted to try the experiment. Perhaps he has already done so, and I should be glad to hear his experience or opinion of the process.

Mr. W. LANT CARPENTER said that a few years ago he had some experience in the working of the process of purifying water from sulphates, which was brought under his notice in Germany. It consisted in the simultaneous use of either milk of lime or lime water and chloride of barium, and in agitating the water with these. Practically it was a process especially adapted to water to be used in boilers, and the most convenient mode of agitating the water was found to be the use of a steam injector carrying in a blast of air with it, which gave very effectual agitation, and also warmed the water. By bringing the water to about 105°F. the precipitate settled very rapidly. No filtration was necessary for this purpose, and a boiler fed with it worked for a year continuously, without showing the least sign of incrustation. It might be urged that chloride of barium was an expensive salt to employ, but its cost was saved many times over in the diminished consumption of coal necessary to evaporate the water in a clean boiler, with no non-conducting material interposed between the source of heat and the water.

The CHAIRMAN said this was a most interesting description of a process which certainly ought to be much more widely known. Clark's process was inapplicable, except in special circumstances. It might do very well for the vast storage reservoirs of a water company, but nowhere else. Mr. Porter had shown an exceedingly neat application of the same chemical principle to the ordinary needs of manufacturers or smaller places.

#### REPLY.

Mr. PORTER said: With regard to the cost of treating very much larger quantities of water than those required for manufacturing purposes, he had not yet dealt with a larger quantity than one ton of water per minute. No doubt if they had much larger quantities to deal with some economy could be effected in the relative capacity of the vessels, in the cost of the filter presses, and also in the amount of labour employed, and probably the cost would come down to half the present cost. What he always told the water companies was that they charged the public for filtered water but did not filter it. The whole point between the public and the water companies was that the water was not sufficiently filtered.

Another point was this: the water companies grumbled about paying a farthing or a halfpenny for a thousand gallons, but he contended the water he used cost him about 3s. per 1,000 gallons; and taking houses of a higher rent than his, such as those in Belgrave Square, the figure would probably work out very much higher still. With regard to the apparatus lending itself to the use of other reagents, there was no doubt it would do so, and this matter had been lately brought to his attention by one of the insurance companies. Nearly all sulphates of lime and magnesia could be treated with chloride of barium, but the great difficulty of these things was the cost of material. Lime only cost about 15s. a ton.

Mr. MEADE said he understood magnesia stone could be got for 3s. 6d. a cwt.

Mr. PORTER said that seemed a reasonable price, but whether the magnesia was in a form suitable for the purpose he was not chemist enough to say, but it would be objectionable if the magnesia, like soda, remained in solution, as it might cause "priming" in the boiler. He had never tested the commercial value of the precipitated carbonate. From the London and North-Western works in Liverpool they took it to Crewe to mix with clay for brickmaking. At the India-rubber works it was used instead of whiting for paying over the cables.

## NOTE ON THE PRINTING OF NATURAL INDIGO ON CALICO.

BY ROBERT BOURCART.

THIS style of printing, as it is done at the works of Messrs. Schlieper and Baum, Elberfeld, has been very obligingly communicated to me by Mr. Adolf Schlieper, who ordered a great variety of pieces to be printed in my presence, and has given me the following indications, with permission to communicate them to those interested in calico printing. Printing by natural indigo has long been practised, and many works use a process described in the treatise of Persoz, which consists in throwing down white indigo with tin crystals, and printing in an acid state. The combination of white indigo with tin is decomposed when the pieces are suspended in the air, and indigo fixes itself on the fibres. Nevertheless, by this process only light blues can be obtained—sky blues; but dark blues, as produced by dyeing in the indigo vat, cannot be

made by this process. Artificial indigo made with orthonitrophenylpropionic acid, which is called in the trade propiolic acid, is far more expensive. It can only be used for small designs, and even if its price were not a hindrance a very dark blue could not easily be obtained. Moreover, when it is printed in somewhat heavy designs, the unpleasant smell of xanthate of soda, with which it is fixed on cloth, reappears again, notwithstanding the most energetic washing with hot water or sodium carbonate. The process of Messrs. Schlieper and Baum allows of printing a blue colour with natural indigo. This colour can be made light or dark as is wanted. It is identical with dyed blue, called dip blue, for shade, and costs less for the same darkness. It has, therefore, a great future before it. The details which follow are all necessary to make a good colour. They must be followed exactly, because the smallest fault makes the printing fail; but if the work is carefully done a very regular and fine blue is obtained. First of all, a special arrangement is wanted. Erect a small shop to print the blue, with one or two machines; surround it with partitions to avoid draughts; heat it in the winter, like an apartment. Each printing machine must be accompanied by a steam chest, and by a small drying machine to dry the cloth before printing. It must be, besides, furnished with a special drying apparatus, with hot air blown from a Root's blower. The doors of the workshop must slide up and down, to avoid all displacement of air. (See Fig. 1.)

The principle of the Schlieper and Baum process is as follows: Glucose in presence of alkalis is an energetic reducing agent chiefly in the heat, and in contact with steam at 100°C. The reducing agent acting upon finely ground indigo transforms it into white indigo, which is dissolved by the alkali which is present, and is immediately fixed on the vegetable fibres, which are possessed of a special affinity for reduced indigo. Water is then powerless to carry off the indigo. Cotton has been dyed in the same manner as hanks of wool or silk, which have been dipped into a solution of aniline colours. By washing the glucose and soda are then carried off, and soon, in contact with air, the blue develops itself. It is oxidised again, and then withstands perfectly all soapings, alkalies, and light—the latter, however, bleaches slowly indigo. For printing indigo a very thick colour is made, containing very concentrated caustic soda, indigo in the state of a paste—that is, very finely ground with water—and a thickening (mixture of roasted Indian cornstarch and Indian cornstarch). This colour must be very thick, because it must be simply deposited on the surface of the fabric, and not permeate it. The cloth is previously padded in a solution of glucose, then carefully dyed, so that the alkaline colour and glucose are superposed, but not mixed in the printing.

To dry the pieces the greatest care must be taken. They must be dried slowly, as much as possible with hot air, and not be allowed to remain in contact with hot plates or cylinders, otherwise the soda will destroy the indigo before reduction takes place. It must also always be verified if the dried piece contains a trace of moisture. If it is completely dry, or if it has been too much heated for a single moment, the colour is much weakened. The temperature of drying must never be above 75°C. Steaming is carried out immediately after printing. For that purpose a special box is used, which is placed immediately behind the printing machine, and care is taken that the pieces be dipped in an atmosphere of pure steam completely deprived of air. The soda then attracts water, penetrates the cloth prepared with glucose, and reduces the

indigo, which the fibre absorbs immediately. The pieces must come out of the steaming a brown colour with an olive tint. If they are yellow it is because they have been dried too much before steaming, and they will only give in that case a very pale blue. After steaming, the pieces are immediately washed with special care, much water being employed, the soda and glucose being carried off. There still remains on the cloth a trace of soda, which causes the blue to oxidise quickly in the air, and therefore is beneficial. The cloth is again washed with water,

# I.—INDIGO ALONE.

## Preparation of the Printing Colour (Standard Colour).—Receipt—

25 kilos. indigo.  
100 kilos. water.  
50 litres caustic soda, 70° Tw.  
58.53 kilos. solid caustic soda, 90 per cent., sufficient quantity to change the 100 kilos. of water into alkali, specific gravity 1.35; together with the 3.75 litres water which are employed to prepare the printing colour.

Grind in an indigo mill 25 kilos. indigo (standardised

Fig. 1.

The Root blowing machine is in the washing-room. The dotted lines, which in the designs come from the apparatus, show the way followed by the hot air at the top of the printing-room. A is the only piece marked, which is on the ceiling; it represents five rotatory winces of polygonal shape.

Fig. 2.

and afterwards dried. During the drying the oxidation of the blue is completed. To avivate or brighten this, it is treated at the boil with a weak solution of caustic soda, which replaces soap with advantage. (See Figs. 2 and 3.)

The following is a description, with details, of the steam indigo process as it is practised by Messrs. Schlieper and Baum, at Elberfeld: (1) Indigo alone. (2) Indigo on turkey-red. (3) Indigo on turkey-red mordant. (4) Resists under steam indigo, two-colour designs, and half resists.

Fig. 3.

at 70 per cent. of pure material by mixtures of various kinds together) with 50 to 70 parts of water. The best qualities are those which are tender. Java is the best of all, and costs eight shillings per pound. When the indigo is ground, which occupies two days, enough water (which is first used to rinse the mill) is added to make up 100 kilos. Then the 125 kilos. are put on a balance having on one side weights and on the other an iron pan suspended in the midst of an empty trough. This trough can be, when needed, filled with cold or tepid water. Then

the alkali is added (sp. gr. 70° Tw.), and then, at once, 58·53 kilos. solid caustic soda, broken up in lumps varying in size from that of the fist to that of a nut. After that it is stirred with a spatula of iron, and care taken that the temperature does not ascend higher than 40° C. If the mixture becomes hot, cold water is introduced into the trough, and finally the latter is filled with tepid water at 40° C. The standard colour, when ready, is put into cast-iron boxes of about 25

Or per kilo. of colour—

	Grms.
British gum.....	55
Indian corn starch.....	27

*Remark.*—The colour must be such that the caustic soda which it contains, compared with the total quantity of the colour, stands at 65° to 70° Tw. These two limits must not be passed, neither must they be fallen short of. Caustic soda, 70° Tw., of specific gravity 1·350, represents 440grms. solid commercial

Fig. 4.

kilos. capacity, of which the lid lutes itself in a circular gutter containing water, intended to prevent the access of air, which contains carbonic acid, and which combining with soda would give crystals. The printing colour is also kept in these boxes. Messrs. Schlieper and Baum make 250 kilos. standard colour at one time. The vessel in which this mixture is made is therefore very large. It is hooked on to an

Fig. 6

caustic soda to the litre. To make the printing colour, 3 kilos. pale British gum (roasted starch half soluble in water) are mixed with 1·5 kilo. Indian corn starch and 3·750 kilos. cold water, in a pan standing in a cold water-bath, then half a litre caustic soda, 70° Tw., are added, and stirred for ten minutes with a wooden spatula; then again half a litre is added, and the stirring is repeated precisely as before, though

Fig. 5.

iron balance, and is suspended inside a wooden trough made of cask sides. (See Figs. 4, 5, 6, and 7.)

#### Printing Colour.—

	Grms.
Pale British gum.....	3,000
Indian corn starch.....	1,500
Water.....	3,750
Caustic soda, 70° Tw.....	19,000
Standard colour.....	27,000
Total.....	54,000

Vessel with hydraulic lid

Fig. 7

very slowly. As it is useless to stir it all the time, a man can mix three colours at once. Finally the standard is added. The quantity of soda for a very dark colour will be, for instance, 19 kilos., and that for the standard 27 kilos. These proportions can be varied according to the intensity of the blue wanted, but the sum of the quantities of caustic soda (70° Tw.) and standard must always be 46 kilos. The colour with 18 kilos. of standard is still

very dark, and costs 2s. 3½d. per piece of 66 yards. The thickening per piece is reckoned at 4d. The colour with 33 kilos. of standard is nearly black. Colours are named by giving them a number showing how many kilos. of standard are contained in 54 kilos. of printing colour. When all the soda as well as the standard is added to the thickening, which takes about two hours, it is heated quickly to 70° C. in the water-bath and well stirred to make the mixture more homogeneous; it is then rapidly cooled in the cold water-bath. Afterwards the colour is placed in the above-described iron pots. Before printing it is strained through sieves, by hydraulic pressure, or through bags, between two wooden sticks. The colour must always be very thick, which does not prevent it printing well, because it is also very smooth. When heated a little it becomes more fluid and oily. This result is also obtained by stirring with a spatula. This colour keeps for several months, but after such lapse of time it must be heated very slowly, and stirred strongly before using it. The colour must always be printed slightly tepid, and rollers and boxes must be made lukewarm before using them.

from the roller, and touches directly the warm plate. The back cloth and gray cloth are dried behind the machine by passing between hot plates; but the piece, on arriving at the top of the room, undergoes a special kind of drying. In the other room is machinery blowing hot air, which sends air at 75° C. through a tube of the size of a common stove pipe. At the top of the room, under the ceiling, is a threefold box, somewhat wider than the piece, and nine yards long. The cloth goes three times this length, descending each time from one box into the other, the warm air accompanying it; then it goes out, and is deposited in folds on a table. There the workman must continually try with his hand what is the amount of moisture still present, and quicken or slacken the speed of his piece to suit the quickness of the drying. For blue alone, it is dried in such a manner that to the touch it is very slightly moist and gummy; for blue on turkey-red, on the contrary, it must be dried more, and to the touch must be nearly dry. Same recommendations for blue with sulphur resist, so that the resist cannot run into the blue.

*Steaming.*—The cloth must be cold before steaming,

Padding machine

FIG. 8.

*Preparing of the Cloth in Glucose.*—(Solution of glucose, 12° Tw.)—The cloth must be passed into a solution of glucose by means of the preparing machine. The solution of glucose (12° Tw.) contains 250grms. to the litre of water. Care must be taken that the cloth goes several times up and down the rollers, before being squeezed out. For cloths dyed in red, special attention must be given to them becoming thoroughly saturated. Therefore a hot solution of glucose is used, because these kinds of cloths, being oiled, are very difficult to wet thoroughly. After that they must be dried and wound up. In preparing, attention must be given that lint does not remain sticking on the cloth, because it would be very difficult to remove afterwards with the revolving brush. The cloth must be dried a second time before printing, glucose being hygroscopic, and the piece, when printed, must be very dry, and rather warm. (See Figs. 8 and 9.)

*Printing of the Colour.*—The printing colour is very thick, and the printer must stir it constantly with his spatula. The printed cloth moves along a lukewarm steam plate, which ascends to the ceiling. It leaves its back cloth a few inches

Machine for drying cloth a second time before printing

FIG. 9.

because if it is warm the soda does not condense enough water in passing through the chest. It must be steamed immediately after printing. The steam chest is of wood. It is 5ft. high, without counting the base, which is of iron, and contains water, above which are two or three sieves. Above the steam chest is a steam plate, which is 10in. wider on each side. The steam, after having passed in this plate, descends into the lower part of the chest and comes into the water. On its way it receives, on both sides, steam from two small pipes placed at the entrance and at the exit of the pieces. These pipes are placed in such a manner that the piece immediately before entering, and after coming out, passes over them. They protect it from the moisture of the steam, which is condensed by the air in coming out of the box. The steam plate must also, for the same purpose, reach 10in. out over the entrance and the exit of the cloth. The piece, before and after steaming, ascends a steep incline, not to be moistened by the steam, which, coming out of the sides, ascends in a kind of funnel of canvas into a chimney, which draws it outside. The steam which condenses on the canvas cannot fall upon the pieces, there being other sheets of wet canvas below the

former, and two gutters for carrying off the dropping water. In the steam chest are rollers below and above. The piece ascends and descends in twenty seconds, and then passes out and falls in folds into a canister. All the machinery is in a special room, screened with glass partitions all round, to avoid draughts, and the doors slide up and down. There are in this room two printing machines, producing 25,000 pieces of 66

minutes. During this time they pass five strong waterjets which throw water from above. There are five large compartments furnished with rollers at the top and at the bottom. Between the boxes there are squeezing rollers, which forward the pieces from the one into the other. The dung beck is 8 yards long and 4ft. high. Nine-tenths of alkali are here washed off, and what remains

Fig. 10.

Apparatus for steaming the indigo

Fig. 11.

yards in the year, chiefly plain pads for discharge work with pigments, albumen, and chromate of potash. (See Figs. 10 and 11.)

**Washing.**—When the pieces are steamed they are carried into the washing-room on the other side of the glass partition. There they pass first in the open state through a large fly dunging machine (see plan of works), in passing through which they take two

can do no harm, because the piece is at once forwarded to the washing machine. There would be more alkali taken off if the dung beck contained rotatory winces, which would beat and shake the cloth, just as they do in the endless open soaping machine. At the end of the dung beck the pieces are pressed between the two last squeezing rollers, so that the water will not prevent

the oxidising action of the air. They then pass over five cylinders with rods fixed at the ceiling, whose work it is to shake them in the air, after which the pieces fall in folds on the ground. When about 35 yards have been passed, the pieces are put in communication with a washing machine of the usual construction. The pieces are previously formed into a rope, by passing through several porcelain rings, and then washed successively through two washing machines of middle size, for five pieces of 66 yards. Then the cloth is dried on a drum, where the oxidation of the colour is completed. It is not yet lively, and to activate it the cloth is passed into a boiling solution made of 500 litres of water and 5 litres of caustic soda, 45° Tw. The colour then becomes bright, because the soda carries off a brown colouring matter. Besides this, soda carries off less blue than soap does, and is cheaper. The cloth is again washed and dried, and the pieces are ready.

red. But for this, acid treatments are required, which all kinds of turkey-reds could not withstand. To print the blue, the red pieces are prepared like the white ones, with a very hot solution of glucose, and by passing repeatedly on rollers before squeezing out (see sketch of the preparing machine), so that a complete moistening can be attained. After printing, the pieces must be dried more than for blue on white cloth, because all the strength of the alkali is required to destroy the red, but a very slight trace of moisture must be felt still. Then they are washed in the fly dung beak and washing machine and dried on hot cylinders, the same as before. They afterwards pass through another dung beak (see plan of works), which is in the dyehouse. This has three compartments. The first contains sulphuric acid (10½° Tw.) The cloth passes, in seven or fourteen seconds, to the shade of blue required. The first shade has a slight purple cast; the second is bluer but a little

Fig. 12.

Fig. 13.

Blue 27 is the ordinary colour, and costs about 3s. 1½d. per piece of 66 yards, whilst the dip blue of the same intensity costs 3s. 7½d. This blue can be used for discharge styles; but if plain pads are wanted, a colour of half strength should be printed twice over, as this would make the shade more even;

Sample No. 1.

Printed indigo, with reserve in the engraving or the roller, but all operations, preparing of cloth included, would be needed to be repeated twice over. (See Fig. 12 and sample No. 1.)

#### II.—INDIGO ON TURKEY-RED.

This process depends upon the fact that by suitable operations the alkali of the blue destroys turkey-

red. lighter, whereas the Turkey-red ground withstands perfectly.

The second compartment is somewhat larger, and contains water, to wash off the acid. The third is smaller, and contains carbonate of soda 3° Tw. Its alkalinity is scarcely felt with the

Sample No. 2.

Turkey-red cloth, printed in indigo

hand. This last compartment is very small. It has two pairs of rollers, the middle one six and six and the first one three and three. Between them are squeezing rollers, which forward the pieces from one into the other. The goods are afterwards strongly soaped at the boil with soap, when the latter becomes quite purple, and finally the pieces are washed and dried. (See Fig. 13 and sample No. 2.)

## III.—INDIGO ON TURKEY-RED MORDANT.

This process aims at sparing alizarin, because where there is blue the mordant is destroyed before fixing any colouring matter. (a) Preparing of the mordant. (b) Printing of the blue. (c) Discharging of the mordant. (d) Dyeing in red. (e) Brightening of the red.

(a) *Preparing of the Mordant.*—The mordant is an aluminate of lime. First, aluminate of soda is printed on, which is made as follows: Take dry alumina from the "Chemische Fabrik zu Niemburg an der Wesel." It is a nearly pure hydrate of alumina,  $(Al_2(OH)_6)$ . Forty kilos. of this substance are heated for three hours with 64 litres of caustic soda at  $35^\circ$  Bé (about  $50^\circ$  to  $55^\circ$  Tw.), and then diluted to the volume

that it is dunged in a chalk beck for twenty minutes, to give back to the mordant the lime which sulphuric acid has taken away.

(d) *Dyeing in Turkey-Red.*—For dyeing, very large troughs are employed—about  $5\frac{1}{2}$  yds. long, 5 ft. high, and 7 ft. wide, without compartments. The pieces pass open, same as in the fly dung beck.  $1\frac{1}{2}$  grm. of alizarin (10 per cent.) are added to every litre of water, and for every grm. of alizarin (10 per cent.) there are added, first, 4 grms. saturated lime water (1 to 800), and afterwards again as much in the course of the dyeing. The liquor has a brown colour, and as the pieces pass along, alizarin and lime water are added, according to the quantity, known beforehand, which each piece absorbs in passing through the dye beck. The

Fig. 11.

of 300 litres with water. This soda must correspond litre for litre with hydrochloric acid (sp. gr. 1.15). After this, 8 litres of hydrochloric acid are added. In this manner there are still 56 litres caustic soda not neutralised in the liquor. It is then diluted to the volume of 620 litres with water. This aluminate, to be good, must be still able to receive 30 c.c. of hydrochloric acid, (1.15 sp. gr.) without losing its clearness; if not it must be exactly adjusted by adding either hydrochloric acid or caustic soda. Then for every 4 litres of mordant 1 or, better, 2 litres of water are added. It is blotched and dried on drums. The cloth turns yellow. It is passed for twenty minutes through the ageing-room system of Walter Crum—that is, in a moist and warm atmosphere, where pieces ascend and descend on rollers. After that they are left lying in bundles from 12 to 36 hours, and then washed in a

duration of the passage is from 3 to  $3\frac{1}{2}$  minutes, and the pieces come out dyed at the other end. For dark pads the cloth is dyed twice over, but they are aivated between the two dyeing operations. The temperature of the liquor is  $90^\circ$  to  $95^\circ$  C. Before being brightened the red is of a dark-brown colour, but it is very able to combine with the acid soap which we describe further on. Care must be taken not to bring the liquor to a boil, because in that case the red would not combine any more with the brightening soap. This is a very interesting operation, because it offers all the advantages of rapid work, fastness, fine shade, and cheapness united. (See Figs. 14 and 15.)

(e) *Brightening.*—The cloth is padded in acid soap. The latter is used instead of oleine. It is made by preparing, first, the soap of castor oil and soda, and neutralising afterwards exactly half of the soda

Steaming cylinder with its warm

Fig. 16.

Fig. 15.

fly dung beck and pass through a washing machine for half an hour in a lukewarm bath containing a good quantity of chalk. They are afterwards washed slightly with water, much chalk being left on the cloth. After that the pieces are heaped together for 24 hours in the wet state, then the chalk-bath is repeated, and they are allowed to lie for 24 hours again. The mordant is then completely transformed into aluminate of lime. Lastly the pieces are well washed, and they are ready for dyeing. If chalk were not employed, the red or the mordant would not at all be able to withstand the action of sulphuric acid.

(b) *Printing of the Blue; and (c) Discharging of the Mordant.*—The blue is printed in the same manner as on a dyed red, and it undergoes the same operation of washing and passing into sours. After

with hydrochloric acid. Acid soap is a liquid which floats on the surface of the trough where it is made, and below is the solution of sodium chloride, which has been formed by adding hydrochloric acid to the soap ley. The red cloth saturated with this liquid is dried on drums, and then steamed. Steaming is continued for one hour, at  $\frac{1}{2}$  lb. pressure, in horizontal cylinders arranged in rows, and into each of them is introduced a small wagon, running upon rails, and furnished with ropes, made of goats hair, on the top. On these ropes the pieces rolled on themselves, are suspended, so that they hang off about  $3\frac{1}{2}$  ft. After steaming, they are again soaped and washed. The steaming, for an unknown reason, is always somewhat hurtful to the blue; therefore a very dark colour must be employed, that it may be still dark after having lost somewhat

of its strength. For instance, blue No. 27 will give a blue No. 20 or 18, which is still of good depth. (See Fig. 16.)

#### IV.—RESISTS UNDER BLUE.

**White Resist.**—This is done with precipitated sulphur, which is bought from De Haën in Hanover, and which is prepared by means of the polysulphide of sodium. This precipitated sulphur, which contains always sand, is ground in a small mill with a solution of British gum. It is afterwards thickened with British gum by taking 140grms. sulphur per litre. This sulphur, when indigo is printed on and steamed, is changed into polysulphide of sodium, which prevents the fixation of the colouring matter. To receive this resist the pieces must be well dried before printing on the blue, that the design be neat. (See sample No. 3.)

Sample No. 3.

Cloth printed in indigo and sulphur resist, and covered in indigo.

**Yellow Resist.**—200 grms of cadmium chloride are mixed with the above colour. In contact with sodium hydrate, sulphur dissolves and forms yellow cadmium sulphide. (See sample No. 4.)

Sample No. 4.

White and yellow resist under printed indigo.

**Resist with a Mordant for dyed Alizarin Red.**—This is more difficult to make, because only acid or neutral drugs can be added to sulphur. If the required mordant is employed, which would be aluminate of soda, the rollers and copper-faced doctors would be soon destroyed, copper sulphide being formed. With acid mordant, on the contrary, alumina formed from the acetate would be at once washed off in contact with the caustic soda dissolved from the piece in the first beck of the fly dunging machine, at the commencement of the washing. A special arrangement must therefore be devised. In the first compartment of the dung beck (see Fig. 12, No. 1 compartment), a weak solution of arseniate of soda and sal-ammoniac, to the extent of 200 grms. per litre, are added, and care is taken to add enough to compensate for the quantity which the piece carries away during the course of the washing, notwithstanding the rollers which squeeze the liquor out. One litre is lost for every eleven yards of cloth. In this operation a double exchange takes place immediately between the soda of the cloth and the sal-ammoniac. Sodium chloride is formed and ammonia is set at liberty, and this ammonia does not dissolve alumina. When the liquor smells too strongly, ammonia is neutralised with hydrochloric acid. The piece passes afterwards through water (compartments 2, 3, 4, and 5) as in other resists. Generally, how-

ever, there is in No. 5 a weak solution of silicate of soda to give the cloth an alkaline reaction, and so allow the blue to oxidise quickly in the air. When there is not much blue printed on, and consequently little alkali, there is no need of using any sal-ammoniac. Compartments 1, 2, 3, and 4 contain, then, only running water, and No. 5 a solution of silicate of soda (3° Tw.), which acts as a dung for alumina, and prevents it from running. The red is dyed as described before. The mordant must be somewhat concentrated, and contain about 10 grms. per litre of tin crystals. (See sample No. 5.)

Sample No. 5.

Printed in white and red mordant resist, printed in indigo, dyed in red, oleined, steamed, and soaped.

**Designs with Two Rollers (Red and Blue).**—This style resembles very much the one above. The best plan is to use alkali red mordant (aluminate of soda), because acid mordant marks off on the second roller for blue, and precipitates itself on it as hydrate of alumina, fills the engraving, and consequently makes a light blue mark on the piece, repeating the design on the first roller. Alkali red mordant, on the contrary, answers the purpose, if care be taken not to steam more than 20 seconds; then the pieces are passed through sal-ammoniac or silicate of soda, according as there is more or less blue on the cloth. These styles of red and blue are very expensive when it is needed to employ sal-ammoniac in the beck.

**Half Resist.**—If colour 0 be employed (i.e., without any standard colour in it), and this be steamed, all the glucose is destroyed, and is no more able to fix any blue. But if, on the contrary, an alkali of weaker strength is printed on, the glucose will only be partly destroyed. On that rests the printing of all shades of half resists. After steaming, the pieces must simply be dried on the small cylinders for drying prepared pieces; then the blue is printed as on other resists, and then steamed and washed. (See sample No. 6.)

Sample No. 6.

Cloth mordanted for red, prepared in glucose, printed on with strong alkali; steamed, dried, printed in indigo; steamed again, washed, dried, soured, dunged, dyed in red, oleined, steamed, and soaped.

#### GENERAL REMARKS.

1. The great future of printed indigo depends upon the fact that it is less expensive than dip blue. All discharges which are made on the latter can also be made on steam indigo blue, and in that case it needs not to be printed twice over, as with plain pads.

2. To destroy the blue on stained pieces and bleach them, Messrs. Schlieper and Baum boil them in a small kier with red prussiate and permanganate of

potassium; but it would be easier to bleach them by enclosing them in one of the large kiers in the bleach-house, and heating them there for seven hours, at 50lb. pressure, with carbonate of soda and resin. In that case they come out at once thoroughly white. This process is also good for pieces dyed in dip blue. It seems that indigo can withstand pretty well strong alkalis, even if warm, at the ordinary pressure, but with three or four atmospheres even carbonated alkalis destroy it.

3. Indigo can be very well printed on linen, and in fact is so printed in England at the present time.

#### DISCUSSION ON MR. BOURCART'S PAPER.

Dr. HURTER supposed the great advantage of the process described was the facility with which the pattern was printed, whereas formerly it had to be dyed. Dr. Bourcart had mentioned the necessity of not having the goods too dry, as otherwise the caustic would destroy the indigo, but what about the cotton itself? He would like to know if the process described would compete with the printing with artificial indigo, or would be likely to supersede it? From the samples shown by Dr. Bourcart it would appear that the very finest patterns could be printed, so that in this respect the new process could compete with the propiolic acid process.

Dr. BOURCART: Formerly there were no means of obtaining a dark shade of indigo, and this was provided now by Messrs. Schlieper and Baum. He had submitted a sample of cotton printed with indigo to the microscope, the caustic soda used in the process having been extremely strong, 65° to 70°Tw. Nevertheless the cloth was not destroyed at all. He had observed, moreover, that the threads were perfectly dyed. Propiolic acid is only used by calico-printers on a very small scale, and then there was a great disadvantage owing to the bad smell imparted to the cloth, which often prevented customers from buying it.

Mr. W. D. HERMAN: Does it retain the smell long?

Dr. BOURCART: Several years, I think.

February 6, 1884.

MR. E. K. MUSPRATT, IN THE CHAIR.

#### THE LANCASHIRE SODA TEST.

The CHAIRMAN announced that Mr. A. Norman Tate, who had promised to read a "Note upon the Lancashire Soda Test," was unable, from indisposition, to attend. In his absence he (the Chairman) would read a letter he had received from Mr. Tate. The following letter was accordingly read by the Chairman:—

"I am sorry that, being confined to the house in consequence of indisposition, I shall not be able to be present to read the 'Note on the Lancashire Soda Test,' and not being able to get access to some papers and journals that I wished to allude to, I cannot send you a full note that might be read by some person else. I would, however, say that my object in reading the note was to call attention to some remarks made by Mr. John Pattinson, analyst, of Newcastle, at the meetings of the London Section and of the Newcastle Section (both meetings are reported in the last *Journal of Chemical Industry*). Mr. Pattinson states that the Liverpool soda test is from 1 to 3 per cent. higher than the Newcastle test. Mr. Davidson, of Newcastle, also stated that he had found differences, and that samples divided into two portions had given different results by Newcastle test and by Liverpool test, Liverpool being 48 per cent. against 45 and 46 in Newcastle. In vol. 32 of *Chemical News*, page 267, Mr. Pattinson made a similar statement, and a long discussion then ensued, in which I took part, when Mr. Pattinson then stated that he did not refer to any tests made by me. Whether this is the case now or not I cannot tell from Mr. Pattinson's remarks, as reported in the *Journal*; but as he speaks generally of 'Liverpool tests,' I wish to say, as one making a fair number of such tests, that the basis on which I work is precisely the same as that given

by Mr. Pattinson, and referred to fully in tables he has published, viz., that the ratio of the commercial test to that based upon the equivalent of soda last adopted is  $37:31 = 31.307$  (or  $31.11:31$ ). Mr. Pattinson, in his tables, gives the same ratio, or rather practically the same,  $31.41$  to  $31$ . It is, therefore, difficult to see where, if the samples are really the same, so wide a difference as even 1 per cent. can occur. If such differences are the rule in the tests of one and the same parcel, I would suggest that sampling and not testing is at fault. However, I regret that I cannot be present to discuss the matter fully this evening, but trust I may be allowed an opportunity at the next or some future meeting. I would, however, lose no time in denying, so far as I am personally acquainted with the matter, that these wide differences can exist when careful sampling and testing have taken place, and this care is taken fully, as far as my experience goes, in Liverpool. The practice of reporting in whole number referred to by Mr. Pattinson could not at any time show a greater difference than 0.5, or not fully that, per cent., and this difference is as often in favour of buyer as seller. Further, a chemist must have unbounded confidence in his own skill if he can state positively to 0.1 per cent. the strength of a parcel of many casks of soda-ash or drums of caustic soda that he has sampled and tested. The practice of reporting in whole numbers, as a matter of chemistry, in connection with the commerce of such articles as carbonated soda-ash, caustic soda-ash, caustic soda, etc., is, to my mind, the most prudent, common-sense, practical method. Personally I do not have two standard acids in my laboratory for testing alkalis. I invariably use a strictly normal standard (for too many standards lead to confusion), and when making a commercial soda test I use a special weight strictly in accordance with the figures I have already referred to, and which are the same as Mr. Pattinson's. This also is done to avoid error from using wrong weights."

The Chairman proceeded to say he thought it very important that the Section should express itself upon the remarks which had been made by Mr. Pattinson at meetings of two other Sections of the Society. He was sorry to find that Mr. Pattinson, Dr. Lunge, and other Newcastle chemists, had made the statement that the Lancashire soda test differed from the Newcastle test by some extravagant figure of 3 per cent. He thought that was unjust and that they had not spoken with the accuracy befitting scientific men. One of the advantages of a society of this kind was that they did inculcate accuracy about statements they made. As Mr. Tate said in his letter, the whole difference between the Newcastle test and the Liverpool test could only amount at the outside to one-half per cent., and the methods of testing were the same; standard acid used was practically the same, and therefore any greater difference that might arise must be either from the sampling or from the personal error of the operator. Now he had yet to learn that it was absolutely impossible for an operator in Newcastle to make a mistake. It was probable that a Newcastle chemist, when he came to test a sample of soda ash, was as liable to error as a Liverpool chemist. They were assured by Mr. Tate—and he thought they would receive similar assurances from other analysts in Liverpool—that the method employed was practically the same, that the only difference was in the way of reporting, and it was well that the statement made by Newcastle chemists should be denied authoritatively from this Section. He would be glad to hear any observations that members might have to make.

Mr. HUSON said he had come that night for the purpose of stating that it had been the practice of his firm (Huson Brothers, Liverpool) to base their tests on the assumption that pure carbonate of soda contained 59½ per cent. of soda, which was the custom generally in Lancashire; and on reading through Dr. Hurter's paper some short time ago he wrote to him pointing this out. They decided the letter should not be published, because the remarks were simply incidental, his paper being not on the Lancashire soda test but another subject, and therefore the letter was not sent to the Society's journal. But he believed Dr. Hurter had now brought the letter with him and would read it. He quite agreed with the chairman's remarks about the possibility of Newcastle gentlemen being in fault, and did not see why Liverpool should be altogether to blame for the difference.

Dr. HURTER said shortly after the December num-

ber of the journal was published he received the following letter from Mr. Huson:—

"In the account of the discussion on the subject of international standard methods of sampling and testing commercial products which took place on the 7th ult., which appears in the number of the *Journal of the Society of Chemical Industry* just to hand, and which we have read with considerable interest, we find a statement to the effect that the Lancashire test is based on the assumption that pure anhydrous carbonate of soda contains 59.81 to 59.69 Na<sub>2</sub>O. As a very large proportion of Lancashire-made alkali has for many years been tested by us, we think it right to state that in our case the above figures are erroneous. Our test is, and always has been, based on the assumption that pure anhydrous carbonate of soda contains 59.26 per cent. Na<sub>2</sub>O. This statement, to the writer's own knowledge, applies to a period of over twenty years back from the present."

He had in his paper made the statement that the atomic weight of sodium varied from the year 1810 to the year 1883 in such a manner as to include differences of 59.8 per cent. to 58.4. What he meant to say was that the mere variation of this atomic weight produced quite as great differences as could ever be observable between the Lancashire test and the Newcastle test. He quite agreed with the chairman that the various gentlemen who from time to time had written to the *Chemical News* had been unduly severe on Lancashire manufacturers as well as the Liverpool analysts. He thought Professor Lunge had been very indiscreet in mentioning names, especially in the German edition of his book on the alkali manufacture. It was utterly impossible that there should be 3 per cent. of difference, even if the Liverpool analysts had used the larger equivalents, which they say they had not used. Even in that case the possible difference between the two tests could only be 0.4 per cent., and such a difference as 3 per cent. was perfectly absurd, and pointed to an error either of sampling or manipulation. All he hoped was that the movement now in progress to bring about uniform methods in sampling and testing would end these everlasting discussions about the Liverpool and Newcastle tests.

Dr. CAMPBELL BROWN said he had been an on-looker in this dispute for the last 20 years without taking part in it, but he had felt very strongly the propriety, to use no stronger word, of the proposal which had been made by Dr. Hurter this year, that all persons interested—manufacturers and analysts—should agree to use the proper scientific figure for the atomic weight of sodium, and conduct all tests and estimates of value upon the best and most accurate figures which had been ascertained up to the present time. He hoped the Society of Chemical Industry would make an effort to have a national if not international agreement as to the conduct of tests upon certain methods which were known to be the most accurate.

The CHAIRMAN thought the discussion on Mr. Tate's note would set the matter right, and he thought it was also a very strong argument in favour of what they desired to bring about, viz., some agreement as to the mode of testing, and what methods should be adopted.

#### DISCUSSION ON MR. WATSON SMITH'S PAPER.

The Section then proceeded to the discussion of Mr. Watson Smith's paper upon "The Tars from Coke Ovens, Blast Furnaces, and from the Sutherland Gas Producers," read December 5th, 1883, and January 7th, 1884.

Mr. DOUGLAS HERMAN thought the sample of tar tested by Mr. Watson Smith could scarcely be considered as fairly representing the quality of tar capable of being produced by the Sutherland process, for the reason that the condensation was inefficient, owing to shortness of water. The temperature of the water running from the condenser averaged

143° F., and the liquor in the well 117°. Under these circumstances it could scarcely be expected that benzol, even if formed at all, and the more volatile oils should be present, especially if the large volume of gas, something like 150,000 cubic feet to the ton of coal passing off at this high temperature, be borne in mind. To show the effect of even a trifling improvement in the condensation, he might mention that for some time the production of tar was barely 4 gallons to the ton of fuel; but by slightly increasing the quantity of water to the condenser, and causing some to flow through the hydraulic main, the yield was increased to 8 gallons, and even then there was undoubtedly a large quantity of tar passing away with the gas.

Dr. HURTER spoke of the difference of opinion as to the conditions under which certain tar contained the valuable constituents, benzol, etc., and under which it did not. In some books it was stated that the lower the temperature of distillation the more benzol was got, whereas in other books the opposite was asserted. His own opinion (the reasons for which he gave) was that the view that the lower the temperature the more benzol was produced, was absolutely wrong.

Dr. Hamburger and Mr. Allen (Sheffield) followed

#### REPLY.

Mr. WATSON SMITH: In reply to Mr. Douglas Herman I should not like to say much until I have tested a better condensed sample of tar from the Sutherland producers, but I think I may speak to the strong probability of the lower boiling naphthas in well-condensed Sutherland producer tar, consisting chiefly of lower paraffins and olefines, with a certain small proportion possibly of the benzene group of hydrocarbons. The similar nature of this tar to that of the tar of the blast furnaces, as regards its higher boiling constituents, points unmistakably in this direction. Referring to the remarks of Dr. Hurter, with regard to the possibility of drawing anything like a sharp line, and defining rules for so carbonising fuels as to obtain fixed products, that lies only within narrow limits. Not only must the carbonising temperature giving certain results be kept constant, but the carbonaceous material used must not vary, must also be constant, and even then the products will be to some extent mixed. I will try to illustrate my meaning. The same coal carbonised in closed gas retorts at high temperatures, and giving normal coal tar, would at comparatively very low temperatures give a tar of low specific gravity, resembling the tar of the Scotch shale distillers. The first tar is rich in benzene and its homologues: the latter contains little of these, and olefines and paraffins take their place. Anthracene has disappeared, and in its place solid paraffins appear. Again, if Wigan cannel be used solely for gas-making, whatever temperatures are employed, the tar will be found to contain some solid paraffins deteriorating the anthracene. Hence tar distillers often stipulate in their contracts with gas companies that not more than a certain percentage of cannel shall be mixed with the coal carbonised in the retorts. As regards benzene and its homologues, those high temperatures in carbonising coal in closed spaces, which aid in generating benzene and its homologues; and phenol, cresol, naphthalene, and anthracene, if they are carried higher and become very high temperatures, then benzene, toluene and xylene become scarcer, phenol shares their fate, whilst naphthalene and anthracene increase and become abundant. But though in distinction to the highest temperatures, those found to yield benzene and its homologues, with carbolic acid, most abundantly, may be termed "lower temperatures" yet, in

comparison with the lowest temperatures of destructive distillation at which paraffins and olefins are almost exclusively yielded, they are justly termed "high temperatures." In reply to Dr. Hamburger, it is true that certain tar constituents cannot be so exactly measured and estimated in a laboratory distillation of even 4 litres of tar at a time. This quantity, however, we can and do distil in the laboratory of the Owens College by the method I have recommended, in thin glass retorts, and with perfect safety and ease, but I should prefer a distillation from a 10-gallon still, for in our case, using only 4 litres say, of normal coal tar, when the small quantity of crude benzol we obtain is treated with acid and alkali and rectified, a further classification into 90 per cent. and other grade benzols becomes nearly impracticable, the quantity has so dwindled down. In order to get the percentage of 0.75 of real anthracene, in the Simon-Carvès tar, *I did not include* the stuff obtained by coking the pitch, and found by Versmann to be so very impure. What I analysed was a perfectly normal and workable "thick oil," only it contained less liquid oils than ordinary anthracene oil does—in fact, it precisely resembled the best anthracene oils, after having been on the filters some time. With regard to Mr. Allen's suggestion as to heating petroleum oils strongly, I may just say that the processes originated by Liebermann and Burg and Letny, and afterwards carried out in South Russia, near Baku, for obtaining anthracene, etc., by passing Caucasian petroleum residues through red-hot tubes, were given up. The fact is, all methods based on the passing of oil vapours through red-hot tubes are exceedingly wasteful, owing to the incomplete nature of the decomposition to yield any one specific substance, and the large separations of carbon taking place. It is very interesting to hear that a chemical investigator has obtained a small quantity of a new hydrocarbon by such work with red-hot tubes, but to prepare such a hydrocarbon on a manufacturing scale would be to the manufacturer neither profitable nor interesting.

method, another reaction comes into play. The same is true of my process of titrating oils, which, indeed, is the case referred to by Dr. Armstrong, who appears to have overlooked the fact that an excess of hydrochloric acid is always present, and hence it is not a solution of a hypobromite which is in question at all, but the products of its decomposition by hydrochloric acid. If the solution of bromine in soda be freshly made, the reaction with hydrochloric acid may be represented by the equation—

Now, if the solution of bromine in soda be stale, a more or less perfect conversion of the hypobromite into bromate and bromide will have occurred, and hence in old solutions the action of hydrochloric acid may be formulated as follows :—

Hence, theoretically, the whole amount of bromine present in the liquid will be liberated on adding excess of hydrochloric acid, and it becomes a matter of indifference whether the bromised soda be fresh or stale. This fact has been clearly recognised by the compilers of the new German Pharmacopœia, who prescribe the employment of standard solutions of bromide and bromate of potassium in conjunction with acid for the titration of phenol.

The facility with which the reaction resulting in the liberation of bromine will occur, and the completeness of the change in the cold may be open to question, and I have therefore made some experiments on the subject.

The solutions of hypobromite were made by dissolving bromine in excess of cold solution of caustic soda. The strength of each solution was then ascertained by measuring out 5c.c. with a pipette, diluting with water, adding potassium iodide solution and excess of hydrochloric acid, and titrating the liberated iodine by decinormal solution of thiosulphate. Operating in this way with three solutions of bromised soda I obtained the following results, calculated on 100c.c. of the solution:—

NOTE ON THE STABILITY OF HYPOBRO-  
MITE SOLUTION, AND ITS USE FOR THE  
TITRATION OF OILS, ETC.

BY ALFRED H. ALLEN.

THE reaction of bromine on caustic soda is well known to result in the formation of hypobromite and bromide of sodium, in accordance with the equation  $2\text{NaHO} + \text{Br}_2 = \text{NaBrO} + \text{NaBr} + \text{H}_2\text{O}$ . Gradually in the cold, but rapidly at a boiling temperature, a further change occurs with formation of bromate and bromide, thus—

Owing to this tendency to rearrangement, hypobromite solutions are generally described as quickly changing in strength, and Dr. Armstrong expressed this view in discussing the recent paper by Messrs. Mills and Snodgrass, "On the Quantitative Estimation of Oils and Fats."<sup>\*</sup> Of course such a change will be important if the hypobromite be used as such in the presence of excess of free alkali, as is done in estimating urea; but when the hypobromite solution is employed in conjunction with excess of hydrochloric acid, as in the assay of carbolic acid by Koppeschaar's

Bromised Soda.	Grammes of available Bromine per 100c.c. Solution A. Solution B. Solution C.		
Freshly made, contained ..	12.98	13.18	12.37
Boiled 5 minutes without dilution ..	12.92	..	..
Diluted and boiled 5 minutes ..	12.91	12.88	..
Diluted and boiled 1 hour .....	12.80	12.61	..
Diluted and boiled 3 hours .....	12.60	..	..
Diluted and boiled 4 hours .....	..	12.56	..
Kept 3 weeks, contained .....	..	13.12	..
Kept 8 weeks, contained .....	..	..	12.46
Kept 8 weeks and boiled 15 mins.	..	..	11.65

Most of these experiments were made in duplicate. The three solutions of bromised soda presented a notable difference in colour, A being much lighter than B and C, though in each case a fair excess of soda was present. I am at a loss to account for the bright yellow colour of solutions of bromised soda, but it appears to bear a relation to the tendency to lose available bromine by boiling. The colour often becomes deeper by keeping, so that it can scarcely be due to hypobromite.

In the foregoing experiments the caustic soda employed was not weighed, but in the case of a fresh solution (D) 62.20 grms. weight of bromine was dissolved in a solution of 45 grms. of pure caustic soda made from sodium, which is a considerable excess, 31.1 grms. of NaHO being the quantity theoretically required for the reaction  $2\text{NaHO} + \text{Br}_2 = \text{NaBr} + \text{NaBrO} + \text{H}_2\text{O}$ . To insure great accuracy in the experiments with this solution 25c.c. measure was diluted to 250c.c., and 25c.c. of the diluted liquid used for each titration. This volume required about

40c.c. of decinormal thiosulphate. The following results were obtained:—

(D) Bromised Soda—	Available Bromine in 100c.c.	
	Grms.	
Freshly made, contained (two experiments) . . .	12.86	
Boiled for 1 hour, contained . . . . .	12.79	
Boiled for 1 hour, contained . . . . .	12.76	
Boiled for 4 hours, contained . . . . .	12.80	

In this case the strength remained practically unchanged even after prolonged boiling, and yet the original solution was decidedly yellow. Hypobromite in solution is supposed to be readily and completely changed by boiling into a mixture of bromate and bromide, and the foregoing experiments were conducted on this assumption. As the result of direct experiment, however, I subsequently found that the solutions, after dilution and boiling for one hour, still gave a copious dark brown precipitate with manganese sulphate, and evolved gas when warmed with urea. Hence the hypobromite in a strongly alkaline solution of bromised soda is not readily destroyed by boiling. To ascertain whether this unexpected stability was due to the presence of caustic soda, this was removed from a quantity of hypobromite solution by adding an excess of magnesium sulphate solution and filtering the liquid. The liquid thus neutralised still had an alkaline reaction to litmus, but had a marked bromous odour which the original had not. It gave an abundant dark brown precipitate with sulphate of manganese, but five minutes' boiling usually sufficed to destroy every trace of hypobromite, so that hypobromite is readily and completely transformed by boiling in neutral solution. It must be borne in mind, however, that these experiments were practically made on hypobromite of magnesium, where, as in the former experiments, the sodium salt was employed. On boiling, the neutralised solution evolves a very notable proportion of bromine or compound of bromine capable of liberating iodine from potassium iodide, but the free bromine in the distillate, together with the available bromine in the liquid remaining in the flask, do not together amount to the full proportion of bromine contained in the solution before boiling.\* Still, the deficiency is not very great.

On the whole, therefore, it appears (1) that the presence of excess of caustic soda greatly increases the stability of hypobromite solutions. (2) That most solutions of bromised soda lose a little of their available bromine by boiling. (3) That the solution of bromine in excess of caustic soda solution has, after boiling, all the practical advantages which would be possessed by a concentrated solution of free bromine not liable to loss by volatilisation or change in strength by keeping.

A curious oversight of the advantages attaching to a solution of bromised soda over mere bromine water occurs in the reply of Messrs. Mills and Snodgrass to the discussion on their paper already referred to. These chemists describe the employment of hypobromite solution, together with excess of hydrochloric acid, as "an astonishingly roundabout way of preparing bromine water;" but the fact is that the use of hypobromite and acid affords a ready means of obtaining the necessary bromine in presence of a far smaller quantity of aqueous liquid than is the case if mere bromine water be employed. Thus nearly 300c.c. of a standardised solution of bromine water would be necessary for titrating 5c.c. of oil of turpentine, the solubility of bromine in water being only

about 3 per cent., whereas the solution of hypobromite I usually employ contains 12 per cent. of bromine, and can readily be made much stronger. Hence a much smaller volume is required for the titration, and the standard solution is not liable to lose strength by exposure to air, as would be the case with mere bromine water. In their reply to the discussion on their paper (page 438 of last volume), Messrs. Mills and Snodgrass state that "the bromine-water method or moist process was communicated by one of us to Mr. Allen in 1880 (Oct. 7th)." There is a mistake here, the origin of which I am wholly unable to trace; but, as a matter of fact, I had given a description of the results yielded by the process in a paper read before the Pharmaceutical Conference in August, 1880, and published in the *Pharmaceutical Journal* for September 25th, 1880, which latter date was twelve days before the communication is stated to have been made to me\* (October 7th, 1880).

The method I have employed for preparing the solution of bromised soda has incidentally furnished a determination of the density of bromine. The plan adopted has been as follows: About 40 to 45grms. weight of pure caustic soda were dissolved in water, and the solution was placed in a flask and accurately weighed. A quantity of bromine was shaken with powdered potassium bromide, water added, and the shaking repeated. The bromine was drawn off from the aqueous liquid, shaken with water, separated, and then agitated with concentrated sulphuric acid. By this treatment it was hoped to purify the bromine from any chlorine it might have contained, and also to render it perfectly anhydrous. The purified bromine was next run into a burette, and from that 20c.c. measure was run into the soda solution, and the increase of weight noted. In this way the weight of 20c.c. of bromine at the ordinary temperature of the laboratory was accurately ascertained, and in three experiments was found to be 62.261, 62.381, and 62.202grms., the mean being 62.281. This would correspond to a density of 3.114 if the weight of 20c.c. of water at the ordinary temperature had been strictly 20grms., but with a correction based on the actual weight of water delivered by the burette, the density of the bromine at the ordinary temperature works out to 3.177. I do not claim rigid accuracy for this determination, but it is of interest as approximately confirming the result of Pierre (3.1872 at 0°C.), while it is at variance with the figures of Balard (2.966) and Löwig (2.98 to 2.99 at 15°C.).

There is one curious fact in connection with these experiments for which I am unable to offer any explanation of a satisfactory nature, and that is that in each case the proportion of bromine found in the bromised soda by titration is sensibly in excess of the weight actually employed. Thus:—

	A.	B.	D.
Bromine employed, by weight . . . . .	12.432	12.929	12.440
Bromine found, by titration . . . . .	12.98	13.13	12.86

As to the cause of this discrepancy, (1) the precautions taken to purify the bromine used in making solutions A and D seem to negative the presence of chlorine as an impurity; (2) in each case the thiosulphate solution employed for the titration was most carefully set by resublimed iodine; (3) the potassium

\* The theoretical bearings of the decomposition of magnesium hypobromite with evolution of more or less bromine, and the quantitative experiments required for the elucidation of the reaction, I propose to make the subject for a future paper.

\* The following is a passage which occurs in the paper mentioned in the text: "Those products which are most readily acted on by nitric acid also have the greatest capacity for decolorising bromine water, and I am attempting to base a method of determining the olefines on this principle. The results already obtained in this manner are very remarkable, and conclusively prove the predominance of olefines in shale products, these readily decolorising many times the volume of bromine which can be caused to combine with petroleum naphtha or burning oil."

iodide employed was free from iodate; (4) any inactive impurity in the bromine, such as bromoform, bromide of carbon, water, or sulphuric acid, would tend to reduce its titration-value as compared with its weight; (5) the presence of iodine would operate in the same direction.

#### DISCUSSION ON MR. ALLEN'S PAPER.

Mr. WATSON SMITH: A stable solution of sodium hypobromite of known strength means an available bromine solution of known strength ready at any moment. Such a solution may in the future furnish a useful means for titrating certain naphthas (*e.g.*, shale spirits) for their content of olefines, adding the bromine so long as quickly absorbed without formation of hydrobromic acid. A method based on this principle has, I believe, already been foreshadowed by Mr. Allen.

Mr. ALLEN said he had described a method of employing bromised soda and hydrochloric acid for the titration of shale-products, in his work on "Commercial Organic Analysis."

Dr. CAMPBELL BROWN thought that a new determination was wanted of the atomic weight of bromine.

Dr. HURTER said that the loss of strength alluded to in the paper was also found in boiling the hypochlorites. They found there was not the amount of chlorate present that would correspond to the original amount, and they always put it down to simple escape of oxygen. He confessed himself quite unable to account for the loss in weight Mr. Allen had spoken of.

### AN ATTEMPT TO UTILISE WASTE HEAT BY PERKIN'S PIPES.

BY FERDINAND HURTER, PH.D.

THE utilisation of waste heat forms the subject of many inventions and of many disappointing experiences. To save heat does not always mean a saving of money. An apparatus which pays at one place does not pay in another. Whether the utilisation of waste heat is equivalent to a saving of money depends entirely upon the work which has to be done and upon the price of coal. It is impossible to settle the value of waste heat generally. But for particular applications its cost can be ascertained—for instance, for its application to the evaporation of liquids; and it will be found that for this purpose waste heat will not often mean a great saving of money. Assuming that the waste heat itself has no value, its cost will be the cost of the apparatus by means of which we utilise it. Supposing that depreciation, repairs, rates, and taxes, ground rent, supervision, etc., are covered by the modest sum of 20 per cent. per annum on the capital outlay, the cost of waste heat per annum would be one-fifth of capital employed in utilising it. Every square foot of heating surface of sheet iron transmits per hour as much heat as would heat 4lb. of water by 1° C. where there is 1° difference of temperature between the two sides of the heating surface; consequently per year of 300 working days that square foot of heating surface would transmit 3·12 ton units of heat (1 ton unit equals as much heat as would raise the temperature of 1 ton of water by 1° C). But if the difference of temperature were any other number, say T degrees, then the number of ton units transmitted per annum would be 3·12 × T. Now, this quantity of heat costs one-fifth of the capital spent upon one square foot of the heating surface. The least amount of money for which any apparatus

for evaporation per square foot can be erected is about 4s. to 5s., including mounting, brickwork, etc., consequently the cost of 3·12 × T ton units of heat costs from 9½d. to 1s.

Let us now see what in actual practice 1 ton unit of heat direct from coal costs us when applied to evaporation of water in a boiler.

Supposing that a good boiler, capable of evaporating 36 cubic feet of water, costs us £400, and that it evaporates per annum of 300 days 7,200 tons of water, using 1,200 tons of coal, we have the following annual charges:—

Interest, etc. (20%).....	£80
Coal at 5s.....	300
Man for firing .....	25
	£105 = 97,200d.

The evaporation of 7,200 tons of water requires 3,859,200 ton units of heat. Thus, 1 ton unit costs us nearly one-fortieth of a penny. If, therefore, 1 ton unit of heat gained from waste heat must not cost more than 1 ton unit of heat gained directly from coal, it is necessary that the temperature of the waste heat be such that the fraction

$$\frac{9\frac{1}{2}d.}{3\cdot12 T} = \frac{1}{40}d. \text{ or that } T = \frac{40 \times 9\cdot5}{3\cdot12} = 120^{\circ} \text{ C.}$$

This fraction shows that unless the difference of temperature between the two sides of the heating surface be at least 120° C., the waste heat will cost more than the heat from coal direct, if that can be obtained at 5s. a ton, of such quality that one ton will evaporate six tons of water in an ordinary boiler with ordinary firing. Thus in this country the utilisation of waste heat, if it must be a saving of money, requires that the fuel gases from which this heat must be abstracted shall be at a temperature of at least 220° C. or 428° F. You will perceive that if the temperature approaches this the money saved by utilising the heat is a very small amount indeed. This limit, beyond which the utilisation of waste heat costs more than the heat is worth, rises as the cost of the apparatus rises. Where coal is more expensive the utilisation of waste heat of a lower degree of temperature is a feasible undertaking. If I now say that per 1ft. heating area Perkin's water-heating apparatus, as applied to evaporation, costs 8s., you will readily perceive that there is no great inducement to try that system, unless the temperature of the waste heat be more than 800° F., or local circumstances render it specially favourable as compared with other apparatus.

In Leblanc soda works there is a great amount of waste heat at disposal, and in Messrs. Gaskell, Deacon, and Company's works, where special processes are in use, the question arose how to utilise the waste heat of a revolving black-ash furnace. The hot gas from the revolver was first passed through the internal flue of a large boiler, and then by means of a flue of 12ft. width and 3ft. depth under a wrought-iron concentrating pan 36ft. in length. The total amount of heating surface thus disposed for the utilisation of waste heat was 830 square feet. But the quantity and intensity of waste heat from even small revolving furnaces is such that these 830 square feet were inadequate and only reduced the temperature of the fuel gases to about 1,000° F. It was therefore desirable to increase the heating surface, but owing to the already inconveniently crowded state of this part of the works it was impossible to simply add the cheapest form of evaporating apparatus, an iron pan. Consequently it was decided to enlarge the heating surface by placing into the flue, under the pan, a series of coils of pipes on Perkin's high-pressure system. Design and execution were left to an

engineer experienced in constructions of this kind. After mature consideration the following arrangement was decided to be carried out: Six separate systems of coils were used. Each system consisted of two coils, one placed into the flue under the pan the other into the pan. The length of the coil in the fire was 160ft., that in the pan 70ft. The aggregate length of all the coils was 1,380ft., and the heating area 360 square feet. Each coil was provided at its highest place with an expansion vessel, and at its lowest point with a kind of ball valve, through which the pipes were filled with water. The pipes were very strong,  $1\frac{1}{2}$ in. outside and  $\frac{3}{4}$ in. inside diameter. The joints were made as usual in this kind of apparatus, the end of one pipe being sharpened to a knife edge and hardened, meeting the flat and soft end of the pipe to which it was to be joined, the one pipe having a left-handed and the other a right-handed thread. The two pipes were screwed together by a coupling, which had corresponding threads, and by means of very powerful tools the knife edge was driven into the flat end of the pipe to be joined. The six coils in the flue were placed across the flue supported by suitable frames. Opposite each coil was a door to clean the pipes from flue dust. The coils in the pan were placed at the bottom of it lengthwise. Each system contained, when full, about 1 cubic foot of water, and it was calculated that this water, in circulating through the coils, should reach a temperature not exceeding  $450^{\circ}$  F., and the expansion vessels were so adjusted that they would allow this cubic foot of water to expand. But when the apparatus was started it was very soon found that the water became much hotter than was anticipated. The practical way of ascertaining the temperature consists in filing, at the place at which the hot water leaves the flue and enters the pan, a bright surface on the pipe, and observing the colour which the bright spot assumes. It ought to become straw coloured. But in our case the colour rapidly became purple and blue, and thus all we could ascertain was that the temperature exceeded  $550^{\circ}$ . The first of the coils was also provided with a pressure gauge, but as the index very rapidly moved to the end of the scale 1,500lb. per square inch, we had no means of judging the temperature. The expansion vessels proved too small, and the first and second of the coils, those exposed to the greatest heat, burst during the next twelve hours. According to Hirn's formula, if water is heated to  $300^{\circ}$  C. ( $572^{\circ}$  F.) it will expand nearly 40 per cent. of its volume, from which the expansion of the iron apparatus would have to be deducted. These expansion vessels are a weak spot in the whole apparatus. If they are too large the pressure is too small and the water boils; if they are too small the pressure becomes too large and the pipes burst. When the apparatus had been provided with expansion vessels of sufficient capacity it worked, but it did not work well. The temperature outside the pipes being variable interfered much with the work of the pipes. At times the fluid in the pipes became actually red hot, to judge from the red heat of the pipes which conveyed it from the red coils in the flue to the coils in the pan, and which were quite outside the flue. Very soon the pipes became covered with flue dust, and this interfered very seriously with the amount of heat conveyed. During one experiment I found that instead of conveying 4lb. units per hour they only conveyed about 2lb. units, and probably less. The dust was frequently blown off by means of a steam jet. Then the number of pipes in the flue proved a serious hindrance to the draught. Unless very good slack was at our disposal the revolving furnace got behind in its work. But the most serious drawback was, that although the workmanship was good the coils leaked and gradually got empty; and as they cannot

be refilled except when cold, this leakage meant so serious a stoppage that the pipes had to be removed. This failure, however, is chiefly due to the following cause: The water circulates in the pipes by reason of the difference of the specific gravity of the hot water ascending and the cold water descending. The velocity of circulation depends upon the difference of level between the coils. But it also depends upon the length of the system and the number of bends, and it requires a very careful calculation to find the length of the pipes for any given temperature and any given difference of level. A method of making this calculation is given by Schinz in *Dingler's Journal*, vol. 219, but it is so complicated that I must condemn it as not applicable. I have felt that, failure as it was in our case, the application of this system might still have a future in the utilisation of waste heat; and in order to know the probable cause of the failure, I have taken the trouble to carefully construct formula for the ready calculation of such pipes. I find that in our case the failure was mainly due to too slow a circulation. The difference of level from centre to centre of coil being only 1ft. 6in., the total length of the pipes in each coil ought not to have exceeded 144ft., whereas we had 230ft. Thus we had far too much friction. But the slow circulation in too long a pipe causes a high temperature, a high pressure, and consequently increased leakage and danger to the apparatus.

I shall append tables for readily calculating such systems of pipes. It may be interesting to some to know how far the heat evolved in the fireplace of the revolver was thus utilised. The following figures are approximations as good as I could obtain them. There were burnt per week 120 tons of fuel, including mixing slack, and 114 tons of sodium sulphate were decomposed.

	Ton Units per Week.
Heat produced in fireplace of revolver.....	840,000
Heat utilised in revolver: (a) For decomposition of sodium sulphate and calcium carbonate into sodium carbonate and calcium sulphide.....	188,100
(b) Carried off by fused black ash.....	38,760
	226,860
Heat utilised for evaporation: (a) In boiler (area 396 square feet).....	89,190
(b) In pan (area of bottom, 432 square feet).....	51,990
Assisted by coil area, 360 square feet.....	141,180
Heat lost: (a) By chimney (gas at $800^{\circ}$ F.).....	138,624
(b) Other losses (difference).....	333,720
	472,344
	840,000

When the same revolver was working in the ordinary way—i.e., when its waste heat was utilised for evaporation of vat liquor by surface evaporation—the following figures were similarly computed:—

Heat evolved in fireplace .....	840,000
Utilised in revolver .....	226,860
Utilised in evaporation of vat liquor by 432 square feet area .....	138,624

The two statements compare as follows:—

Percentage of heat utilised by direct surface evaporation, heat passing over surface of liquid, 436 square feet area.....	16.5
Percentage of heat utilised by 1,188 square feet of heating surface, heat transmitted through iron plates ..	16.8
Ton units per square foot of area of liquid exposed to surface evaporation per week.....	320
Apparatus cost per square foot .....	5s.
Ton units per square foot of surface of transmission per week.....	119
A square foot costs .....	9s.

The conclusion is obvious: the cheapest way of utilising waste heat is by surface evaporation, where that is practicable.

The formula I have constructed for the ready calculation

lation of apparatus similar to the one described is, if we denote by—

H = Heating surface of the single coil in the fire.

C = Cooling surface of the coil placed into the liquid.

$\alpha$  = 23 Kilogramme units of heat transmitted persquare metre per degree per hour from the fire to the water.

$\beta$  = 921 Kilogramme units transmitted persquare metre per degree difference from hot pipes to the liquids in evaporating pan.

$T_1$  = Temperature of fuel gas.

$t_1$  = Highest temperature of the circulating water.

$t_0$  = Lowest temperature of water in pipes.

$T_0$  = Boiling point of the liquid in the pan.

$$\delta = \frac{H}{C} = \frac{\beta}{\alpha} \cdot \frac{\log \frac{T_1 - t_0}{T_1 - t_1}}{\log \frac{t_1 - T_0}{t_0 - T_0}}$$

The following table gives the different ratios of heating surface to cooling surface which must be used for different temperatures.

$T_1$ Centigrade.	$T_1$ Fahrenheit.	$\delta$ Ratio $\frac{H}{C}$
1000	1832	3.018
900	1652	3.432
800	1472	3.990
700	1292	4.756
600	1112	5.913
500	932	7.801
400	752	11.515

To obtain values for the absolute lengths of the coils, I have assumed the boiling point of the liquid to be 100° C. = 212° F., the lowest temperature of the circulating water 120° C. = 248° F., and the highest admissible temperature 240° C. = 464° F., corresponding to a pressure of from 500lb. to 600lb. per square inch. I have also taken into consideration the friction of the water in the pipes, but not the bends. Consequently the following values are maxima, and must on no account be surpassed. The formula for the length of the pipes to be placed into the evaporating apparatus is, if D is the diameter of the pipe in inches,

$$C = 37.3 \times D \sqrt{\frac{h}{1 + \delta}}$$

In this formula  $\delta$  has the value given in Table I., and  $h$  is the difference of level in feet between the centres of the coils in the fire and those in the evaporating apparatus. The following table gives a few of these values.

TABLE II.

Showing length in feet of pipes necessary for one unit of Perkin's system (diameter 1in.).

Difference of Level Feet.		1000° C.	900° C.	800° C.	700° C.	600° C.	500° C.	100° C.
2	(C	29.5	28.6	27.5	26.5	24.5	22.7	20.0
	(H	83.0	98.0	110	126	141	177	230
4	(C	37.5	36.4	34.9	33.5	31.2	28.7	25.5
	(H	112	124	139	158	184	221	290
6	(C	43	41.5	39.8	38.1	35.5	33.0	29.0
	(H	128	142	157	180	208	257	333
8	(C	47.1	45.7	44	42	39.3	36.5	32.1
	(H	141	156	176	198	231	282	372
10	(C	50.7	49.1	47.5	45.5	42.5	39.1	34.5
	(H	152	168	188	215	252	305	395

Example: Difference of level between centres of coils equals 8ft.; temperature of flue, 800° C. The table gives opposite 8 and under 800° the two figures 44 and 176, which mean that 176ft. length of coil must be placed into the flue, and 44ft. into the liquid to be evaporated. The water in the pipes is supposed

to have as extreme temperatures 120° C. and 240°, and its volume will be about 1.059 at 120°, and 1.262 at 240°, if the volume at 0° = 1, consequently the expansion vessels must contain 25 per cent. of the volume of the pipes.

#### DISCUSSION ON DR. HURTER'S PAPER.

Dr. CAMPBELL BROWN asked what happened when the tubes burst. He supposed the expansion of the water was so small that the explosion would be of very little effect.

The CHAIRMAN asked whether there was not a deposit on the tubes from the alkaline liquor above them which would obstruct the heat.

Dr. HURTER said the liquor was not so saturated as to deposit salts, and consequently the pipes remained clean. The expansion of water at such degrees of heat would be very great indeed. At 300° C. water was expanded 40 per cent. beyond its natural volume, but in the case of the bursting of a pipe there was very little damage indeed.

Dr. BROWN: No great volume of steam?

Dr. HURTER: Very little. The whole of one of these systems I have described contains about one cubic foot of water.

The CHAIRMAN thought the fact of having tubes filled with red-hot water would be new to most of them, and Dr. Hurter had seen something which few people had seen before.

MEETING TUESDAY, NOVEMBER 6TH, 1883.

### ADDRESS BY THE CHAIRMAN,

I. LEVINSTEIN, ESQ.

THIS Section has been formed for the purpose of more effectually carrying out the principal object of the foundation of our Society,—namely, the promotion and advancement of the knowledge of technical chemistry. That our Society has been thus far successful is generally admitted, but there is still plenty of scope for further improvement and plenty of work to do, and I hope that the Manchester Section, so favourably situated, will lead the way in promoting its principal aims. Manchester, as has been frequently pointed out, is an important chemical centre, many most extensive chemical manufactories being situated within a radius of less than twenty-five miles. We find in its neighbourhood large alkali, soap, acid, and artificial manure works, extensive tar distilleries, aniline oil and coal-tar colour works, etc. Indeed, nearly every branch of chemical manufacture is represented; and if we further take into consideration the numerous important cotton and other industries in which chemical knowledge plays such an essential part—such as printing, dyeing, sizing, bleaching, paper-making, etc.—we may fairly say that Manchester, above all, is the very town where the establishment of a Section of our Society was most desirable; and this was undoubtedly

the opinion also of those who, about nine months ago, bestirred themselves so energetically for its formation. Now, gentlemen, notwithstanding that the prosperity of a manufacturing nation depends to a great extent on the progress of its chemical and other allied industries, we frequently hear from men who ought to be well informed that this country is behind others, not only in the knowledge but in the application of chemistry, which in the case of a great manufacturing nation cannot fail, if it be a fact, to be an extremely disheartening reflection.

We will now consider how far the serious statement relative to our being behindhand in the application of chemical knowledge is correct. If we take into account the very large capital invested in chemical industries, and the very important bearing of the latter on other industries, it will be conceded that we in England ought to watch with the greatest jealousy the progress of other nations, and to examine carefully and apart from prejudice their position as compared with our own. Now as far as any decline or falling behind in chemical industries is concerned it may be some consolation to know that this is principally confined to one special branch, and that the assertion, frequently heard, that we are completely beaten in those industries which depend to a large extent on applied chemistry is as much an exaggeration as would be the assertion that the French can beat the British on the seas. We are often told that the English calico printers cannot print so well as the Alsatians, that our dyers cannot dye so well as the French or Germans; but such indiscriminate statements can be accepted only to a very limited extent. If an outsider, as sometimes happens, picks up one of the very best class Alsatian prints, and compares it, without taking into account the relative cost, with an average English print, and then bases his criticism on such a comparison, he may easily jump to the conclusion that this country is behind others as regards printing. English and Scotch printers and dyers can print and dye, taking price and quality into consideration, equally as good colours as the Continental, and indeed in some specialities they are ahead of any, even the foremost.

We must never overlook the fact that the demand regulates not only the quantity but also the quality of the supply, and I doubt not that if our merchants were willing to pay our printers as good a price as the highest class of Alsatian prints command, and would at the same time undertake to keep their works fully going with orders, the English printers would be able to turn out as good a print as any one. It is at any rate a fact, and one which tests the standard of an industry more conclusively than all the loud assertions about its failings, that the printers of this country supply not alone the principal part of our home consumption but also to some extent the wants of other nations, and that in some classes of prints they are still taking the lead in those foreign markets where prohibitive tariffs do not exclude fair competition. And very much the same thing may be said about the position of the art of dyeing. It is quite true that the Swiss and others produce, on certain classes of goods, rather better colours, but here again it is in many cases a question of price. I know by experience that English dyers can produce far superior colours to those generally met with in the trade, if the merchant could only afford a better price for dyeing; but the prices which dyers have to accept for some colours are so exceedingly low, considering the high wages they have to pay for labour, that it becomes an impossibility to supply the very finest shades. What is generally asked of the English dyer is to turn out quantities at the smallest possible expense consistent with producing passable colours.

So here again it is the demand which regulates the quality of the supply; and in justice to the dyers of this country I must mention that for certain classes of goods even the Germans prefer them to their own dyers, whilst some of the principal concerns in the United States employ Scotchmen and Englishmen as foremen dyers in their establishments.

That this country is foremost in such industries as the manufacture of alkalis, soap, acids, artificial manures, bleaching powder, paper, etc., is also evident, and is proved by the extensive export trade in these different products. The fact that some classes of paper are imported is due to cheaper raw material and cheaper labour, but as far as quality is concerned our high-class writing, news, tissue, and drawing papers rank certainly among the very best produced. We may therefore say, gentlemen, without boasting, that England still occupies a very prominent position in many branches of chemical industry and the manufactures depending on it; and it is only that special part which deals with the production of aromatic hydrocarbon derivatives that has been neglected, and in which this country has allowed itself to remain behind others. This industry, of comparatively recent origin, has already become one of the most important, for not only has it revolutionised the whole art of dyeing and printing, by the introduction of the aniline, naphthol, alizarin, and resorcine colours, but it includes also the production of numerous other compounds of more or less utility to the arts and manufactures and to science. I will only just mention artificial vanilline, artificial oil of bitter almonds (benzaldehyde), carbolic acid, salicylic acid, and kairin, one of the latest discoveries, which promises to be of great service in medicine. The establishment and development of this industry was due to the careful study of the constitution of the aromatic hydrocarbons and their derivatives, a group of chemicals which has supplied the chemist with a wider field for original research, and one followed by more important practical results than most others, and in which are yet hidden the germs of perhaps still more important discoveries. The great commercial importance of this industry may be estimated by the amount of capital invested in it. The yearly turnover represents several millions of pounds, with profits amounting to many hundred thousands (the profits of three large German coal-tar colour companies alone reached last year a million sterling), and we must not forget that this industry is as yet comparatively in its infancy, and that its further development may multiply these amounts many times over.

If we carefully observe the constant improvements which are being made by the Germans in the manufacture of artificial indigo, and at the same time keep in mind the probable great reduction in the price of the aromatic hydrocarbons, such as benzene and toluene, we shall come to the conclusion that its commercial success as a manufactured article and its general introduction to the trade will only be a question of time. If we further consider the recent researches by Skraup, Königs, Fischer, Ladenburg, and others, it is not at all improbable that we may any day be startled by the news that the German savants have succeeded in producing, at a price low enough to compete not alone with artificial indigo but also quinine and the alkaloids of opium, or at least their physiological equivalents. This feat would mean almost incalculable losses to some of the most important colonies of this country.

It would take us too far from our subject to refer to the physiological properties of some of the compounds already produced from the aromatic bases, but it may perhaps interest you to know that the commercial production of one of the most important—that is kairin—is extending. When this substance was first

discovered, and its effects on the human system recognised, it was then thought that it would probably entirely replace quinine.\* You will thus see, gentlemen, that the artificial production of these most valuable and important articles of commerce, hitherto obtainable only through the chemistry of nature, is not so very remote.

It will therefore be self-evident that a sound knowledge of the constitution of the aromatic hydrocarbons and their derivatives is becoming every day of more importance to the technical chemist, and it is unfortunate for this country that just in this very department of chemical knowledge the British chemist has been entirely outflanked by the Germans, who have made the study a speciality, and during the last twenty years have cultivated and developed it in a marvellous degree. You will also agree with me that it is a perfect anomaly that England, the largest manufacturing nation, possessing immense accumulated wealth, with general manufacturing facilities superior to those of any other country, situated geographically in the most favoured position, and, above all, possessing the necessary raw material in quantities sufficient to supply both its own wants and the needs of the world, should be altogether beaten in an industry which had its original development in its own borders, and of which it was indeed the founder. What, then, is the cause of the fact that this country has lost and is still losing ground as regards this special industry? Is it really the want or the insufficiency of our technical schools? I for one must confess that I cannot see how technical schools or an improved general technical education can have much to do with an industry requiring the highest scientific knowledge. Do not misunderstand me. I do not say that the technical schools in this country are as numerous or as perfect as is desirable. On the contrary, I quite agree that a better equipment and an increase of the number of such schools, and, above all, a general reorganisation of the present system of teaching inductive sciences, would prove a great boon to the general industries of this country. What I contend for is that these schools have only an indirect bearing on the question of this country's position with regard to the special industry which is the principal subject of this evening's address.

Only consider, gentlemen, that about twenty-five years ago England founded this industry, and for a number of years maintained her supremacy in it at a time when the educational system and the number of technical schools were far inferior to what they are to-day; and further, that this country has made comparatively far quicker strides in general education and in the foundation of new schools within the last fifteen years than Germany—and yet, notwithstanding all this, the latter has taken this industry out of our hands. The reason of the inferior position at present occupied by England with regard to this industry is not as mysterious as it might at first sight appear. We will now endeavour to trace the cause of this singular deficiency, which in my opinion amounts to nothing less than a national calamity. If in doing so I have to refer to certain matters which may be unpleasant for some, I trust that the vast importance of the subject will plead my excuse, if any is needed. I may, however, assure those who may differ from me that it is very far from my desire to make any frivolous charges, and that my practical and scientific experience, extending over a period of twenty years, as a manufacturer of coal-tar colours and other aromatic hydro-

carbon derivatives, employing a number of English and foreign scientific chemists, has perhaps afforded me special facilities and opportunities of forming, to some extent, a sound opinion as to the reasons of England's deficiencies in this particular branch of scientific knowledge. However, before commencing the consideration of the real cause of this deficiency, I would ask you to carry your minds back to about twenty-five years ago, when Dr. A. W. Hofmann (whose labours in this special department of organic chemistry had already made him famous) was professor at the Royal College of Chemistry. This retrospect will serve two purposes—it will show you, first, the proud position which this country once occupied with regard to this ever-extending industry; and secondly, the very great influence which one eminent teacher exercised in its foundation, and still more in its development. It was to Hofmann that was due the fresh impetus given in this country to the study of organic chemistry. Not only was he himself constantly engaged in original and laborious researches but he possessed also the talent of inspiring his pupils with a like enthusiasm for that department of chemistry in which this eminent worker and teacher obtained an everlasting name. It was in Hofmann's time that one of his pupils, Mr. Perkin, discovered the first practical method of obtaining a colouring matter from aniline—a colouring matter known for some years as Perkin violet or mauve—and the credit of having founded the entire industry of the manufacture of coal-tar colours belongs to England, though it is quite true that Runge and others, long before Perkin, had observed that colouring matters might be produced from aniline and other hydrocarbon derivatives, but it was Perkin who first devised a practical method of obtaining such colours, and to him belongs also the honour of having first produced them on a manufacturing scale, and of having first introduced one of them to the trade.

It was in Hofmann's time that English chemists improved upon the then costly and difficult method of making aniline oil, and so well did they succeed in their efforts that even at the present day the same process, with very immaterial alterations in the apparatus, is still employed. To give you some idea of the estimation in which the skill of the English chemists in this special branch was at that time held by the Germans, I may remind you of a rather amusing episode, which may possibly be yet in the memory of some, when a partner in one of the largest German coal-tar colour companies fared rather roughly at the hands of British workmen, in consequence of his eagerness in trying to obtain, somewhat indiscreetly, information respecting the different processes carried on at that time at a certain works. It was also in Hofmann's time that another of his gifted pupils, Mr. E. C. Nicholson, in conjunction with Messrs. Maule and Simpson, erected the famous works at Hackney Wick. These works, which were carried on under the name of Simpson, Maule, and Nicholson, were for a number of years the most extensive coal-tar colour works in the world, and they and their successors not only supplied this country but also a considerable portion of the Continent and Transatlantic countries with their superior products; and it was at the same works, in connection with Mr. Barnes, that the manufacture of pure aniline, pure rosaniline and its salts, the phenylated rosanilines and their soluble compounds—such as soluble blues, cotton blues, Nicholson's alkali blues—phosphine, Hofmann's violets, etc., were some of them first produced and others brought to a degree of perfection which has not, even in the present day, been surpassed. Hofmann left this country about 1866. A few years

\* In justice to English chemists, I must here not omit to mention the meritorious work of Professor Dewar, on quinine, the basis of kairin, and also the valuable experiments which he made, in conjunction with McKendrick, in order to show the physiological properties of the quinoline and pyridine bases.

afterwards Perkin and Nicholson retired from the business of coal-tar colour makers, and from that time this branch of manufacture has remained comparatively stationary in this country.

The manufacture of aromatic hydrocarbon derivatives requires the highest special scientific chemical knowledge, as it consists of a series of chemical operations which are difficult even for a skilled chemist, who is not a specialist, to perform in the laboratory, and in which chemicals are constantly introduced which are often known only by name to the most experienced chemists, and even to them only as chemical curiosities. Further, in order to keep pace with the continual new improvements and discoveries chemists of the highest special knowledge, and able to strike out new lines, are a *conditio sine qua non*, if this industry is to be carried on successfully. The field of chemical science is so extended, and is constantly extending so rapidly, that it becomes simply an impossibility for any chemist to attain to eminence in every branch, and certainly impossible for a technical chemist to do so. The work must therefore be divided, and just as specialists are becoming more and more in request in medicine, and surgery, and other sciences, even more so are specialists necessary in theoretical as well as in technical chemistry, and it is to their eminent specialists that the success of the German chemists is to a great extent due. The German chemists, appreciating from its beginning the importance of this new industry, associated with capitalists, and ably supported by their eminent specialists and their large staff of pupils, with their minds actively at work in the same direction as their tutors, soon succeeded, after this country lost its only great teacher in this particular branch, in making themselves masters of the field. This really need not surprise us when we consider the extraordinary want of interest displayed in this special direction by the British professors. I do not mean to say that we have not eminent chemical teachers—the names of many will occur to you. But then these gentlemen, though even great organic chemists, are none of them specialists in this particular department of science, and if you desire further confirmation of my statements, I invite you to look through the literature of the last ten years, and to compare the researches and investigations undertaken by the German with those of the English professors bearing on this subject, when you will be quite as much astonished at the overwhelming amount done by the former as at the insignificance of the work done by the latter. Indeed, gentlemen, unless my memory plays me false, I do not remember, during the period referred to, with perhaps few exceptions, any important original research bearing on this subject undertaken by the English professors, and I certainly cannot call to mind any work done by them which has been of practical utility to this industry. That nothing great has been achieved by them in the direction referred to during the last twelve months may be fairly gathered from the presidential address and the papers read in the chemical section of the British Association at Southport; and whilst the Germans are constantly developing this department of chemistry, and are thus extending and cultivating year by year the ground taken from this country, the British are content with simply acknowledging the ever-increasing amount of experimental research in Germany, without making the slightest effort to overtake their opponents, save perhaps by the demand for increased expenditure on technical education or endowments for research.

Having thus endeavoured to trace the cause of the decline of the manufacture of the hydrocarbon derivatives the remedy cannot fail to recommend itself. What are wanted are teachers of the highest talent who have made this special department of chemical science their life-study, men like Perkin, Hofmann, Kekulé, Bayer, Fischer, Victor Meyer, Graebe, Liebermann, Griess, etc., and I venture to assert, without assuming the rôle of a prophet, that with a few such teachers the average English chemist would very soon equal the German in this branch of knowledge, without incurring fresh expenditure for new technical schools and endowments for experimental research. There are at present quite sufficient schools to effect this purpose. We have in this country splendidly equipped chemical laboratories, munificently supported, but whether teachers or pupils are to blame, the results of the teaching of this branch are unsatisfactory. Men are wanted who have made this particular part of organic chemistry their own, and who could guide our young chemists to original work in this direction. Let the proper authorities select the most talented men as teachers. Let them follow the German authorities, who, when a professorship becomes vacant, look out anxiously for men who have distinguished themselves by some important original work, regardless of any other consideration. A striking illustration of this is found in the case of Messrs. Graebe and Liebermann, both of whom were chemists in a printworks at Berlin, when they discovered the process of producing artificial alizarin. Not long after the publication of their admirable work they were appointed lecturers and shortly after professors. Let the right men be appointed in the right places, and not only will this country be able once more to take the lead in an industry for which it possesses every natural advantage, but the arts of printing and dyeing will also be correspondingly benefited. With reference to these latter, I may say that thus far the experience of printers and dyers with the average chemists, trained at even the best British colleges, has not been very encouraging, and they still have to rely principally upon the much-abused rule-of-thumb man; for, after all, a man with experience gained during a lifetime in these trades, even though he possesses no knowledge of the science which has such an important bearing upon them, is still far more useful to dyers and printers than a mediocre average chemist; and this, I believe, is also the universal opinion of the dyers and printers of this country, who, where they do employ chemists, use them, as a rule, simply to test the quality of the drugs required in their business. Such a class of chemists will not do much to advance the progress of these industries. It needs also no great amount of clear-sightedness to perceive that if we can turn out of our universities and colleges not mere testers, but chemists with a superior knowledge of the hydrocarbon derivatives, and especially of the coal-tar colours, which have caused such a revolution in dyeing and printing, and are becoming daily of greater importance, such chemists will not only be far more useful in promoting the advancement of these arts but they will also readily find far more remunerative employment than our present chemists.

However, I do not mean to say, gentlemen, that if we appoint a really eminent specialist, he would retrieve all at once the lost position of this country. What I desire to impress upon you is that such an appointment would be the right step in the right direction. I am quite aware that even with the most eminent men as teachers it will take a few years before England will be able to outstrip the Germans in the race in which she has allowed them to get such

\* "Researches on Secondary and Tertiary Azo-compounds" (No. 2), *Jour. Chem. Society*, Nov., 1883. This paper was read by R. Meldola, the chemist in an English coal-tar colour factory.

a start. The existing coal-tar colour works in Germany are in the hands of powerful companies, employing large staffs of highly trained chemists, supported by the teachers of the various college laboratories, who are further supported by a large number of competent assistants.

In the meantime let this Section do its utmost in promoting the advancement of that industry in which this country has at present unfortunately to deplore its deficiency. Other Sections of our Society are already most ably represented in the alkali and other manufactures; and I have great pleasure in informing you that some gentlemen have been kind enough to promise us for the ensuing session papers bearing on the subject with which, I am afraid, I have already occupied too much of your valuable time.

The CHAIRMAN, at the close of his address, said: I wish to make a few remarks as to the suitability of papers for our Section. Some gentlemen are under the impression that papers are only suitable containing communications of some new discovery or invention. I venture to think that all papers are most welcome contributions which embody the results of experiences gathered by the author in any special branch of industrial chemistry, or which deal with any new branch not fully developed in this country, and, finally, papers consisting of concise compilations, and supplemented by comments on the latest literature of new compounds, which are likely to be introduced into the chemical industries, will be received as valuable to many. Experience gained in any branch of industry is not only valuable to those engaged in this branch, but the same may be many times most usefully transferred to new channels. Communications of this nature are therefore often more valuable to the technical chemist than the mere fact of the discovery of some complicated organic compound, which may probably never enter into the precincts of our works, however important the same may be to the scientist. We ought to draw a distinct line of demarcation between industrial and purely scientific chemistry, and concentrate ourselves on such subjects which only come within our province, and not import matters which are neither intelligible reading to the bulk of our members nor in any way connected with manufactures.

MANCHESTER TECHNICAL SCHOOL, *Tuesday, Feb. 5th.*

MR. IVAN LEVINSTEIN IN THE CHAIR.

## THE SEPARATION OF BENZENE, TOLUENE, AND XYLENE, FROM CRUDE GAS-TAR NAPHTHA AND CRUDE GAS BENZENES.

BY J. VON HOHENHAUSEN.

A NUMBER of valuable papers have lately been read before this Society on the carbonisation of coal with the object of increasing the quantity either of ammonia or of benzene and its homologues, toluene and xylene. I thought, therefore, that it might not be out of place to make a few observations on the processes and apparatus employed in the separation and production of these substances.

Up to quite recently these commercially important hydrocarbons were only produced from gas-tar naphtha, but the carbonisation of coal with the view of obtaining benzene from gas has furnished a new source of supply. The benzene extracted by passing the gas through fatty absorbents and then recovering

it from the latter by distillation, is not pure benzene, but is accompanied, in addition to toluene and xylene, by other compounds, from which the three former may be separated by fractional distillation. The separation can be effected in a similar manner to that adopted in the production of these hydrocarbons from crude gas-tar naphtha. It will therefore suffice to describe the methods and apparatus used for obtaining these hydrocarbons from the gas-tar naphtha.

Crude naphtha, or "first runnings," is a well-known

Fig. 1.

term in the trade, which is applied to the portion first coming over in the distillation of tar. It is generally sold and its value fixed according to its distilling points. The quality of naphtha varies considerably. The following are the distilling points of some fair average naphthas from different places, of which I have used up considerable quantities:—

Centigrade.	Wigan. Per cent.	Yorkshire. Per cent.	Scotland. Per cent.
105 .....	—	4 .....	—
110 .....	4 .....	16 .....	17
120 .....	19 .....	31 .....	38
130 .....	33 .....	47 .....	49
140 .....	45 .....	—	58
150 .....	55 .....	—	69

I have also had an opportunity of rectifying French crude naphthas from the Mines d'Anzin and the Mines de Blanzay, in France, and from the Compagnie Parisienne de Gaz. The following are the results:—

Centigrade.	D'Anzin. Per cent.	Blanzay. Per cent.	Comp. Paris. de Gaz. Per cent.
100 .....	5 .....	11 .....	10
120 .....	21 .....	37 .....	23
130 .....	39 .....	49 .....	55
140 .....	50 .....	59 .....	75
150 .....	60 .....	69 .....	90
160 .....	67 .....	77 .....	98
170 .....	75 .....	85 .....	—

Whatever may be the quality of the naphtha, it ought

Fig. 2.

always to be purified before proceeding to rectify or separate it. The purification consists of washing the naphtha first with caustic soda lye, and afterwards with concentrated sulphuric acid. The quantity of vitriol used in washing depends to some extent on the quality of the crude naphtha, but generally one

pound of vitriol suffices for one gallon of naphtha. A great point is the thorough mixing of the naphtha with the acid, otherwise the solvent naphtha afterwards obtained in the rectification will be apt to turn rather dark after being kept for some time. The naphtha thoroughly washed is then submitted to separation in a dephlegmator. The construction of this apparatus, as used at the beginning of this industry, and still in use in some refineries, is illustrated in Fig. 1. It consists of a wrought-iron still, provided with 5 copper pans *a, b, c, d, e*, of one metre in diameter. Each of these is divided internally by a perforated copper plate. The vapours of the lower boiling naphtha passing through the perforated plates partially condense those of the higher boiling, which thus condensed flow back into the still. Water enters into the outside of pan *a*, and flows over into *b*, and so on until it passes out from *e*. The still is connected with a copper or iron worm, and can be heated by wet or dry steam. When charged, care must be taken to insure continuous and regular distillation. On starting the distillation, dry steam is turned on, and when the distillation begins to slacken—that is, after nearly all the benzene has come over—wet steam is turned into the still, and the distillation continued so long as any hydrocarbons come over. The water may be separated from the naphtha by an arrangement shown in Fig. 2. This is a cistern made of tinplate, which is divided into two compartments, A and B, which are connected by the pipe *a*. The benzene and water run into A. The benzene being lighter then passes through the pipe *a* into B, overflowing at G into receiving cisterns. The water discharges through pipe *b*, the latter being provided with a stop-tap at *c*. If the distillation and separation in the dephlegmator are properly carried out the results will be as follows—Charge: 500 gallons of Yorkshire crude naphtha, which tested before separation

	C.
16 at 110	
34	120
17	130

The first portion, collected from the dephlegmator, by distillation with dry steam, yielded about 250 gallons of the following distilling points:—

	C.
15 at 95	
39	100
75	110
89	120

Such distilling naphtha is called in the trade a 40 per cent. benzene. Several qualities of Wigan crude naphtha gave under the same circumstances the following results:—

SAMPLE A.		First portion collected.	
500 gals. tested.		Yield 200 gals.	
	C.		C.
17 at 110		11 at 95	
38	120	38	100
49	130	73	110
58	140	89	120

68	150		

From these examples it will be seen that a fair average English crude naphtha, yielding about 35 per cent. at 120° C., will give 50 per cent. or thereabouts of commercial 40 per cent. benzene. The second portion collected from the distillation, which contains non-nitrifiable hydrocarbons mixed with some toluene, xylene, and cumene, was generally sold

as solvent naphtha, or was again subjected to fractional distillation, in order to recover some toluene and crude xylene.

A dephlegmator of improved construction is shown in Fig. 4. It is made by Egrot, of Paris, and we will shortly refer to it again. By this apparatus 30, 50, and 90 per cent. is produced in one distillation. Before proceeding to the description of the different systems used for the separation and production of pure benzene, etc., it may be of interest to mention a few practical tests of commercial benzene. The principal points to be taken into account are, (1) specific gravity; (2) distilling points; (3) treatment with sulphuric acid; (4) nitrication of the benzene. The specific gravity of a good commercial 30 per cent. English benzene is generally 0.875 at 15° C., or 60° F.; of a 50 per cent., 0.878; and of a 90 per cent., 0.882. When the specific gravity is lower than 0.875 the presence of paraffin or non-nitrifiable hydrocarbons may be suspected. Most of the Scotch benzene possesses a lower specific gravity than this. The average Scotch benzene has a specific gravity of 0.870, and often contains 7 to 8 per cent. of paraffins. Such benzenes give a smaller yield of their respective nitro and amido compounds; and 100 parts of a fair average English 90 per cent. benzene yield about 150 parts by

Fig. 3.

weight of well-washed nitrobenzene, whilst 100 parts of some 90 per cent. Scotch benzenes do not yield more than 135 per cent. nitrobenzene. A good average commercial 30, 50, and 90 per cent. benzene ought to distil within about the following points:—

90 Benzene.	50 Benzene.	30% Benzene.
Spec. Gr. 0.882.	Spec. Gr. 0.878.	Spec Gr. 0.875.

81 92	68 105	73 110
87 95	79 110	84 115
90 100	85 115	90 120
94 105	90 120	
98 110		

A well-washed and rectified benzene gives with sulphuric acid a dark yellow or light brown colour. A dark brown or even black colour indicates bad washing and defective purification. The sulphuric acid used in these tests always looks rather darker when mixed with 30 and 50 per cent. than with 90 per cent. benzene.

The nitrication test of commercial benzene may be easily performed by putting 100 c.c. in a flask of 500 c.c. capacity (see Fig. 3), and gradually adding to it a cold mixture of 150 grms. nitric acid, 80 Tw; and 200 grms. sulphuric acid, 170° Tw. When the mixture of the benzene with the acids becomes warm, cool it; then add some more of the acid until all is used up; mix well all the time by shaking the bottle, and continue this, after the whole of the acid has been added, until the contents become cold; then separate the acid from the nitrobenzene which has been

formed, wash the latter several times with a dilute solution of caustic soda, and afterwards with water; let the liquid settle for about 12 hours, and then separate the nitro compound. This test is not only important because of its determining the yield of nitrobenzene, but it also gives a fair idea of how the benzene is likely to work on the larger scale. A good quality of benzene should not get hot immediately on a small portion of the acid being added to it at first. If 100 c.c. of nitrobenzene made in the above manner are put in a retort and about 98 per cent. distilled over, the 2 per cent. residue must remain liquid.

A further test of the quality of the benzene to be examined is to distil the whole of the nitrobenzene obtained from 100 c.c. of benzol, and to treat the first 30 c.c. which distil over with 70 c.c. concentrated sulphuric acid, 170° Tw., when the nitrobenzene will dissolve in the vitriol, and all the non-nitrified hydrocarbons will separate. These hydrocarbons are again treated with a small quantity of nitro-sulphuric acid mixture, and in case benzene is present there will be a rise of temperature. The waste acid is then drawn off, and the untransformed hydrocarbons, if any be present, mixed with sulphuric acid, the quantity of hydrocarbon which is not soluble in the sulphuric acid giving the percentage of paraffins present. The specific gravity of nitrobenzene made from 90 per cent. benzene is by Baumé's hydrometer 25°; 50 per cent., 23°; and 30 per cent., 22°. The coal-tar colour manufacture in its present state of development requires aromatic hydrocarbons of great purity. It therefore becomes of the highest importance to employ the most perfect appliances for their proper separation. I thought, therefore, that it might be of interest to lay before you this evening a description of the apparatus best calculated to attain this object. You will notice that the apparatus consists of four parts, (1) the steam still; (2) the rectifying column; (3) the condenser or *analyseur*, as the French call it; (4) the cooler. The differences in the various systems principally used by rectifiers of benzene may be summed up as follows: Savalle, of Paris, passes the naphtha vapours direct into the column, and his condensers, made of copper, are furnished with copper tubes, through which cold air is forced, whilst the naphtha vapours pass round the pipes thus cooled. Egrot (see Fig. 4) condenses the vapours by passing them through a large copper coil fixed in an iron cistern, and through which water passes. Vedles (see Fig. 5) passes the vapours through four copper cylinders, which are surrounded by water. The vapours pass from the rectifying column—first into one of the upper cylinders, then through a large pipe into the cylinder immediately below it, and from thence they pass into the second under cylinders, and from thence into the second top cylinder, and finally into a condenser of the shape of the letter U.

#### J. ADERS' APPARATUS.

Unfortunately I am not able to give you an illustration of this rectifier. I wrote to Aders for a sketch showing the construction of his apparatus, but received the reply that he only supplies a drawing after an order has been given, and as the cost of the apparatus is about £1,000, the expense would be rather too great to incur for the sake of this evening's paper. As far as I can gather from information supplied, Aders does not pass the vapours direct from the still into the column, but conveys them sideways into the rectifier, which I consider an improvement, as the vapours thus do not come into contact with the condensed higher boiling hydrocarbons, which run back from the rectifying column into the still. Aders considers his arrangement of steam coils for heating the

still, consisting of 3in. copper coils with a large number of joints, about 25, as an important feature. His steam-pressure regulator is similar to Savalle's (Fig. 7). In the absence of fuller information, I should not incline to think it an advantage to work with such a number of joints, which are very liable to leakage, especially towards the end of the operation, when the steam pressure is highest. Instead of having coils for heating the naphtha inside the still, I prefer to use a still surrounded by an iron mantle, or a jacketed still as it is called. In such a still the steam can be easily regulated, and so long as it is provided with safety valve, etc., there is no danger. On the other hand, leakages are very serious in the case of internal coils; and there is the danger of loss of material before the leakage is found out, and when the fact is ascertained the whole apparatus must be taken to pieces, which involves loss of time, etc. The condenser of Aders consists of copper tubes similar to those of Savalle, with this difference, that they are supplied with water instead of air. With the limited information which I at present possess I cannot state whether Aders represents his apparatus as an absolutely new construction, but I used a very similarly-constructed rectifier more than five years ago for making pure toluene at Vedles' works, in Paris, of which I will presently give you a description. Nevertheless, it is not my intention to disparage Aders' apparatus. It is in use on the Continent, and, if I am correctly informed, an English aniline company, which has already had one from him, has recently ordered a second one. It is also in use in another works in this country.

In considering the comparative merits of the different systems from the practical point of view, I must confess that I do not think there is any very material difference, either in the results obtained or in the cost of production of the different hydrocarbons; for, after all, Aders does not pretend to obtain more than 70 per cent. of pure benzene from 90 per cent. benzene, and a similar quantity is got with Savalle's and Vedles' apparatus. If it is a question of economy in the erection of plant, and it is intended to make chiefly commercial 30 per cent., 50 per cent., and 90 per cent. benzene, I would recommend Egrot's rectifier, the cost of which is not half that of any of the above-mentioned apparatus.

We will now go more into the details of the construction of some of the so-called column rectifiers, beginning with that of Vedlè.

#### VEDLES' TOLUENE APPARATUS.

This apparatus consists of a wrought-iron double-cased still A (Fig. 6), provided also with a perforated copper coil for heating the contents, when required, by means of open steam. The still is 1,800mm. in diameter and 1,800mm. deep. The still is surmounted by the dephlegmating column B, which is of similar construction to that shown as the benzene dephlegmator. The vapours leaving the dephlegmator pass out by the pipe C and enter the condenser or analyser D, which consists of a cylindrical or square copper cistern, 1,500mm. deep by 600mm. diameter, in which is fixed a number of copper tubes, 1 metre in length and 30mm. diameter. There are about 60 tubes in this analyser, and through them the condensing water is made to pass, whilst the hydrocarbon vapours fill the space around the tubes. The uncondensed vapours pass out by means of the pipe E and enter the cooler F, of similar construction to the analyser D. The higher boiling hydrocarbons, which have been condensed in the analyser, run back through the pipe *a* into the rectifying column. The distillate runs from the cooler F through the pipe H into the receiving cisterns. The condensing water enters the

cooler through the tap J, and is fed to the analyser by means of the tap K. The waste-water pipes may be easily recognised.

When the still A is charged with the residues from the manufacture of pure benzene it is first heated by means of the steam jacket, and finally wet steam is slowly admitted, the progress of the distillation being carefully regulated. When the distillate begins to run slowly, the water supply is slackened by means of the tap K until the water in the analyser D commences to boil. The distillate is collected in separate cisterns, or better in 100 gallon drums, which are numbered and separately analysed. When the distillate begins to run slowly from the cooler F, while the water in the analyser is boiling, the tap  $g^1$  is opened. The overflow of the water now runs away through the pipe connected with the tap  $g$ , the space in the analyser above this being filled with steam. In regulating the taps  $g^2$ ,  $g^3$ ,  $g^4$ , each time the distillation begins to flag a mixture of toluene and xylene is distilling. At the end of the operation the tap K is completely shut and the analyser becomes filled with steam. The distillation of xylene then commences and the operation is concluded when no more comes over at  $142^\circ \text{C}$ . By analysing the contents of the drums the rectifier finds at once which contain pure toluene and pure xylene and which contain intermediate products.

#### EGROT'S SYSTEM.

In this system the dephlegmating column A (Fig. 4) is made of copper 530mm. diameter, the interior being fitted with 22 partitions. C is a copper pipe conducting the vapours from the column to the condenser. The condenser D consists of a large copper coil lying in a wrought-iron tank. E is a tap and pipe connecting the cistern D with the column, and through which water is passed for cleaning purposes. F F F are small taps, which connect the condenser with the tube G. I I I are three-way taps. The higher boiling hydrocarbon vapours, after condensation, run through the tubes F F F into the tube G, and from thence into the column A through the tubes H I I or through the tap J into the cooler L. The three-way taps permit the condensed higher boiling hydrocarbons to run back into the column, but when 90 per cent., 50 per cent., or 30 per cent. benzenes are required the liquids are allowed to run through the pipe K into the cooler L. These taps also permit a portion of the liquid to be run each way. L is a wrought-iron cistern containing the cooler. M is the tube connecting the cooler with the glass test apparatus N, through which the condensed hydrocarbons are run into the receiving cisterns. O is the tap for passing cold water into the cooler, the waste water passing away through the tube Q into the top of the cistern D. The tap for discharging the cooler cistern L is shown at P.

Having had some experience of this rectifier I can testify to its working very steadily. The yield of pure benzene from 90 per cent. benzene is slightly inferior to Savalle's apparatus, and also to that of Vedles. Egrot's rectifier yields 650 gallons from 1,000 gallons charged, and is an admirable apparatus for making commercial benzenes from crude naphtha.

#### VEDLES' SYSTEM.

This apparatus, as sketched, will turn out 8,000 gallons of pure benzene monthly. The still A (Fig. 5) is of wrought iron, 1,800mm. in diameter and 1,800mm. deep, in the inside of which is a copper coil for close steam. Later on I changed this still for one heated by means of a steam jacket, as with the coil there was much trouble, with constant leakages. The still is in connection with the usual dephlegmating column, com-

posed of ten compartments of cast iron 600mm. in diameter. These compartments contain a number of partitions inside them, arranged so that the vapours pass through condensed liquid on each partition. The vapours leave the dephlegmator, and pass by means of a copper pipe into the condenser, which consists of four copper cylinders lying in a square wrought-iron tank. Each of the cylinders is 2,300mm. in length and 400mm. in diameter. The vapours pass into the upper cylinder on the right hand, and descend into that one immediately below it, then to the lower one on the left hand, and after rising into the top left-hand cylinder pass away from this into the U tube, from which the uncondensed vapours pass into the cooler. The vapours which are condensed from the copper cylinders, and also from the U tube, pass back by means of the pipes into the dephlegmator column. The cooler is not a copper coil, but consists of a copper cylinder 2,900mm. long and 400mm. wide, and fixed in a wrought-iron cistern. The water enters at the bottom and runs through the cistern, passing out at the top, and enters the bottom of the tank containing the U tube, and leaving this tank supplies the first condenser containing the copper cylinders with water. It is of great importance that no direct or wet steam be used in the preparation of pure benzene, as the water would condense in the small back-flow tubes, and form a pressure which would prevent regular distillation.

The following table extracted from my diary gives an account of the working of a benzene rectifier (Vedles). The still is charged with 1,000 gallons of 90 per cent. benzene. The distillate is collected in iron drums capable of holding about 100 gallons each. The two first drums contain about 160 gallons distilled under  $81^\circ$ . This portion is put aside until there is a sufficient quantity, say about 1,000 gallons, when it is again separated by distillation. All that comes over between  $81^\circ$  to  $82^\circ$  is commercially pure benzene. The contents of Drum IX. are redistilled with a fresh lot of 90 per cent. benzene. The residues remaining in the still after the fractional distillation has been stopped are transferred to the toluene apparatus (Fig. 6), where pure toluene is separated from them. 1,000 gallons of 90 per cent. benzene, after complete separation, yield about 80 gallons of compounds, distilling  $40^\circ$  to  $80^\circ \text{C}$ .; 710 to 720 gallons of commercial pure benzene,  $81^\circ$  to  $82^\circ \text{C}$ .; 165 gallons of residues or crude toluene,  $100^\circ$  to  $130^\circ \text{C}$ .; 35 to 45 gallons of loss, volatilised during manipulation.

With regard to Egrot's rectifier, which is a very convenient apparatus for transforming well-washed crude naphtha into 30, 50, or 90 per cent. benzene, I wish to add that the hydrocarbons which are condensed during the process of distillation may be conveniently collected in three covered iron cisterns. The first portion of the distillate is run into cistern I., the next into cistern II., the third and last into cistern III. During the distillation samples are drawn and tested, and in this way there is no difficulty in collecting in cistern I. 90 per cent. benzene, in No. II. toluene, and in No. III. solvent naphtha. By then mixing the hydrocarbons from cisterns I. and II. in certain proportions you get the corresponding qualities of commercial 30, 40, 50, or 70 per cent. benzene. The solvent naphtha may be redistilled in the same apparatus for the purpose of separating from it crude xylene. The very best arrangements of apparatus for rectifying do not, however, produce chemically pure but only commercially pure benzene. Chemically pure benzene is obtained by crystallising commercially pure benzene in a freezing mixture. The benzene thus crystallised is known as chemically pure benzene, or as benzene purissimum crystallisatum. Such benzene is a colourless liquid, possessing a specific gravity of

VALVE IN TEST APPARATUS.

0°899 at 0° C., and boiling at 80°5°. Until about eight months ago benzene purissimum crystallisatum, as the name clearly indicates, was considered an absolutely pure product, but about that time the eminent chemist Professor Victor Meyer showed, after a most cleverly-conducted investigation, that even such benzene is not pure, but contains about 0·5 per cent. of a compound hitherto unknown to chemists, to which he gave the name of thiophene. Its chemical composition is  $C_4H_4S$ . It is interesting to note that Mr. George E. Davis, in a paper read in December last, before the Birmingham Section, states that by crystallising gas benzene he separated a compound which, in his opinion, is probably thiophene. Chemically pure toluene is also a colourless liquid, with an odour similar to that of benzene. Its specific gravity is 0°882, at 0° C.; boiling point 111°.

There is no chemically pure xylene produced for commercial purposes. That which is manufactured is sold at a price which precludes its use in commerce. Manufacturers of xylidine buy crude xylene. Such a product distils within two or four

The CHAIRMAN: I think great credit is due to Mr. Hohenhausen for the trouble which he has taken in bringing before the Society in such a clear and elaborate manner the different apparatus used in the separation of the three important aromatic hydrocarbons—benzene, toluene, and xylene; and I also think the information which he has given us must be welcome to all refiners who have not got the most improved appliances desirable to obtain this object. In the present high development of the chemical industries it becomes a matter of necessity to employ the most improved apparatus, otherwise manufacturers will be at a disadvantage in producing pure articles in an economical manner. At present the Germans are the largest buyers of the raw materials referred to, and one would think that it must pay our refiners much better, considering the high freight, etc., to export these products in as pure a state as possible. We have to thank Mr. Davis for the admirable manner in which Mr. Hohenhausen's drawings have been illustrated by means of the lantern. With your permission, gentlemen, we will postpone the dis-

or five or more degrees. Its composition, however, varies, as Mr. Levinstein, who has had perhaps more experience in the separation of pure xylene than any other chemist in this country, will no doubt demonstrate to our satisfaction this evening.

Before finishing this paper I desire to refer to the intermediate products distilling from 40° to 80° C., from 82° to 110° C., and from 112° to 135° C. Rectifiers of aromatic hydrocarbons are dealing to-day with different products from those of 10 or 15 years ago. At that time there was little demand for pure benzene or pure toluene. The commercial benzenes were mostly only the first portion of purified crude naphtha, from which no pure benzene or toluene was separated. Since that time there has been a large demand for pure benzene, pure toluene, respectively for pure aniline and pure toluidine. The question then arises, what is done with these intermediate products, some of which are neither benzene nor toluene, while others contain benzene and toluene mixed with other hydrocarbons or compounds different from benzene, toluene, or xylene. As a matter of fact, there are refiners—let us hope they are only a small minority—who use these intermediate products for the purpose of sophisticating commercial benzenes and toluenes. I cannot, therefore, lay too much stress on the necessity of carefully testing the commercial benzene, and not relying, as is often done, only on the degrees of distillation, and I trust that the few practical tests mentioned will be helpful in detecting such adulterations.

cussion on Mr. Hohenhausen's paper while I read to you a short communication

## ON THE QUANTITATIVE DETERMINATION OF ORTHO-, META-, AND PARA- XYLENE.

BY IVAN LEVINSTEIN.

XYLENE is a hydrocarbon belonging to the aromatic series, but different from benzene. It is known to exist in three modifications, viz.:—

Orthoxylene boiling at.....	141–142° C.
Metaxylene boiling at.....	140–141° C.
Paraxylene boiling at.....	136–137° C.

It is, however, only since 1877 that all these three modifications have been known to be generally present in gas-tar naphtha distilling at from about 134° to 140°. Indeed, in the latest edition of Miller's Organic Chemistry, date 1880, revised by Armstrong and Groves, we read at page 285: "Xylene, from coal tar: The portion boiling at 136° to 140° contains para- and meta- xylene in variable proportions, but usually consists mainly of metaxylene. Other hydrocarbons, however, are present, the nature of which is unknown." This shows that the revisers of this otherwise very useful book were, at the time of writing the paragraph in question, unaware of the existence of orthoxylene in such naphthas, although in the additions, corrections, and cross-references at the end of the book there is a reference on page 1003 to Jacobsen (Ber. 10, 1009). Until a few years ago xylene in an isolated form was not a commercial article, but was met with in variable quantities mixed with other hydrocarbons in solvent

naphtha, a naphtha largely used by manufacturers of indiarubber goods. Suddenly a demand sprang up for xylene pure and simple as one of the starting points for the manufacture of naphthol-xylidinescarlet, and as frequently happens with new products, there was at first some difficulty in procuring it. This difficulty has now been overcome. There is still, however, another remaining, and that is the want of a ready method of determining its commercial value. Xylene is principally produced by fractional distillation of solvent naphtha, or of the higher boiling portion of crude naphtha, and with proper appliances, such as have been shown this evening by Mr. von Hohenhausen, there is no difficulty in obtaining it to distil within two degrees. You might then think that a hydrocarbon boiling at its proper degree would be pure enough for all commercial purposes, and no doubt such is the case with benzene and toluene. It is, however, different with xylene. As I have already stated, there are three modifications of it known, of which the meta is the only one possessing technical value, whilst as far as I am aware there exists at this moment no practical use for the ortho- and paraxylens. Considering then that the distilling degrees of these modifications are so close to each other, and that their relative proportions vary in commercial xylene, you will at once comprehend that it is impossible to separate the different xylenes from each other by fractional distillation, and that the distilling degrees are altogether misleading, so far at least as the composition of commercial xylene is concerned. Notwithstanding this, contracts between buyers and sellers of this article are still being made, probably for want of a better basis of description, by specifying simply the degree of distillation. The wording is generally: "(So many) gallons of xylene of well-washed quality, distilling within (such and such) degrees." The consequence is that buyers with no other specification of the quality of xylene will sometimes find out to their sorrow that they have made a very foolish bargain. I have endeavoured to devise some practical methods for the quantitative determination especially of the metaxylene, which I now have the pleasure of submitting to you.

#### (A) METHOD FOR DETERMINATION OF METAXYLENE.

Take 100c.c. of the crude xylene, heat them at 100° C. in a suitable glass vessel on a sand-bath, together with dilute nitric acid (40 c.c. acid 80° Tw. and 60 c.c. of water) from half an hour to an hour, or until red fumes no longer are evolved, taking care that the acid is thoroughly mixed with the hydrocarbon; then separate the latter from the acid, and add to the mixture of hydrocarbons an excess of caustic soda, and distil the whole by wet steam. The distillate consists of water and metaxylene, mixed with paraffins, which are always present in commercial xylenes. The hydrocarbons are then separated from the water and about  $1\frac{1}{2}$  of their own volume of concentrated sulphuric acid is added and well mixed for about half an hour, when the metaxylene will be dissolved, whilst the paraffins remain unaltered. Instead of distilling the mixture of hydrocarbons and caustic soda, several times washing with the latter will be also sufficient. By deducting the number of cubic centimetres of paraffins from the original measure in cubic centimetres of the mixture you will get the percentage of metaxylene in the crude sample. Dilute nitric acid converts the ortho- and para-xylene into toluic acids, or into their respective nitro-compounds. These are soluble in caustic soda, and remain behind in the distillation, whilst the metaxylene, under the above-mentioned circumstances, is very little altered by the acid, and distils with the water and the paraffins.

#### (B) METHOD FOR DETERMINATION OF PARAXYLENE.

Take 100c.c. of the crude xylene; add to it about 120 c.c. concentrated sulphuric acid (170° Tw.); mix the whole for half an hour or so, or until no longer any crude xylene is dissolved, and allow it to settle. It is advisable to cool the mixture. The hydrocarbons not acted upon, consisting of paraxylene and paraffins, will rise to the top; separate them, and add to them equal volumes of fuming sulphuric acid containing 20 per cent. of anhydride; heat on a water-bath for a short time; then allow the liquid to settle. The paraffins will rise to the top. Deduct the quantity in cubic centimetres of the latter from the quantity of the original mixture of paraxylene and paraffins, and you will get the percentage of paraxylene present in the sample of crude xylene. Ortho- and meta-xylene are converted into sulphonic acids by the action of ordinary concentrated sulphuric acid, whilst the paraxylene is not altered. Fuming sulphuric acid likewise converts the para modification into a sulphonic acid, but does not act on the paraffins. When it is desired to separate the paraxylene from the paraffins without converting the former into a sulphonic acid, and at the same time to obtain absolutely pure paraxylene, I found the following method to give good results: Put a mixture of the two into a glass flask connected with a Liebig condenser, and convey wet steam into it. The first portion distilling along with the condensed steam is principally paraxylene. Separate this from the water, and distil it once more by applying external heat. Collect all that comes over up to 138° C., and put this fraction into a freezing mixture, when paraxylene crystallises out, and in order to obtain it absolutely pure press the crystals between filter paper.

#### (C) METHOD FOR DETERMINATION OF ORTHOXYLENE.

If the crude gas-tar xylene represents a fair average commercial quality, and originates from English tar, the quantity of orthoxylene present in the sample to be examined may be estimated by calculation. Add together the amount of metaxylene, paraxylene, and paraffins determined by methods A and B; the difference between the whole and 100 will give the quantity of orthoxylene. For example, if 100 c.c. of crude xylene were found to contain 47 per cent. of metaxylene, 8 per cent. of paraxylene, 26 per cent. of paraffins, then the quantity of orthoxylene would be 19 per cent.; total, 100. But as dilute nitric acid also alters the composition of other aromatic hydrocarbons than ortho- and para-xylene, such as toluene, cumene, and cymene, and also acts on other compounds which may possibly be present in crude xylene, it will be obvious that such an estimate by calculation can only be approximately correct. Nevertheless, I generally found this method to give fairly good results with unsophisticated crude xylene properly separated from English gas-tar naphtha, as in such xylene there is, as a rule, no toluene present, and only small quantities of compounds acted on by dilute nitric acid. Should it, however, be of importance to ascertain whether the difference, as calculated by method C, really consists mainly of orthoxylene, and whether the quantity thus determined is approximately correct, it will be advisable to proceed as follows:—

Employ part of method B to effect the separation of the paraffins and the paraxylene from the crude xylene; convert the meta- and ortho-xylene sulphonic acids into their calcium and afterwards into their sodium salts; concentrate the solution of the latter, when the ortho-salt will crystallise in large prisms,

while the meta-salt remains in solution; concentrate the solutions still more, and recrystallise the first and second crop of crystals. The ortho-salt will then be obtained in large well-developed crystals. If you concentrate the solution too far, some of the meta-salt will be mixed with it, which, however, will be nearly all removed by recrystallisation. There is no difficulty in distinguishing the large well-defined crystals of the ortho-salt from the indistinct crystals of the meta-salt. I have, however, observed that the complete separation by crystallisation of the sodium salt of the orthoxylylene sulphonic acid from the sodium salt of the metaxylylene sulphonic acid is much more difficult with Scotch than with English xylenes. Some Scotch samples, containing as much as 10 per cent. of orthoxylylene, did not produce as well-developed crystals, even after several recrystallisations, as some English samples gave after only one crystallisation, notwithstanding that they did not contain perhaps more than 3 per cent. of orthoxylylene. The sodium salt of the orthoxylylene sulphonic acid crystallises with five molecules of water. Its formula is—

The difference in the crystallisation of the sodium salt of the orthoxylylene sulphonic acid made from Scotch xylene is very remarkable, and I cannot at present account for it, otherwise than that the Scotch xylene probably contains some non-saturated hydrocarbons or other compounds which dissolve in the sulphuric acid and form sulphates and sulphonic acids, and thus interfere with the crystallisation of the ortho-salt. I have only made a few preliminary tests, but I noticed that the Scotch xylene absorbed much more rapidly aqueous solutions of bromine than the English xylene. In order to establish the true cause of this difference between Scotch and English xylene it would be desirable to investigate the oxidised products obtained by method A and the sodium salts\* of the sulphonic acids obtained by method B. Unfortunately, however, time does not allow me to continue these experiments. I have mentioned this matter to Mr. Watson Smith, of the Owens College, and I am glad to say that he has kindly consented to further investigate it. For all practical purposes, however, method A will be quite sufficient, as it is at present of very little importance to the consumer of xylene how much ortho- or how much para- xylene, or how much of other compounds oxidisable by dilute nitric acid the sample contains. All that he desires to know is the quantity of metaxylylene present in the crude xylene which he intends to purchase; but as method B gives very little trouble I would recommend its use as a means of checking the results of method A.

The table of analyses given below represents about a dozen samples of fair commercial xylenes. The determinations have been made according to methods A, B and C; the presence and approximate quantity of the orthoxylylene has in each case been established by separating and recrystallising the sodium salt of its sulphonic acid. In every instance crystals of the ortho-salt were obtained and further verified as such by analysis. These determinations show that the distilling degrees do not in any way indicate the good quality of xylene. (Compare samples B and L.) Sample L was sold as commercially pure xylene, and no doubt it distilled within 2 degrees; nevertheless it did not contain more metaxylylene than sample I, which was sold at almost half the price, etc. Crude xylene of the same distilling degree and made from English

tar generally contains more metaxylylene than Scotch xylene (compare samples B and F), whilst Scotch xylene and mixtures of Scotch and English are richer of paraxylylene and paraffins, and their specific gravity is lower than that of English xylene.

Sample.	Origin.	19° C. Spec. Grav.	Dist. deg.	Metaxylylene. %	Paraxylylene. %	Orthoxylylene. %	Paraffins. %
A	Pure meta obtained by method A from English crude xylene.	0·8668	112-113	100	0	0	0
B	English (Manchester tar)	0·8629	131-110	87	6	4	3
C	English .....	—	140-143	87	4	6	3
D	English .....	—	141-115	83	5	7	5

Specific gravity of the paraffins, 0·7107.

I must here mention that in all determinations of the distilling degrees of commercial xylene the thermometer was in the liquid—the bulb about half an inch from the bottom of the retort—which practice I would always advise when dealing with mixtures of hydrocarbons or their derivatives. The paraffins separated from a number of samples of crude xylenes distilled, thermometer in liquid, from 145° to 151° C.

I have to thank Mr. George E. Davis for a sample of crude xylene which he obtained by fractional distillation from crude gas benzene. The distilling degrees of this were 138° to 141°. It was interesting to determine the composition of this crude gas xylene, and I give you the result as follows: Metaxylylene, 47 per cent.; paraxylylene, 8 per cent.; paraffins, 26 per cent.; compounds oxidisable by dilute nitric acid, 19 per cent.; total, 100. Unfortunately, I had not a sufficient quantity to regenerate the orthoxylylene from its sulpho-salt; but from the amount of ortho-salt obtained, I estimate approximately that of the 19 per cent. oxidisable compounds 13 per cent. were orthoxylylene. The metaxylylene, paraxylylene, and paraffins were determined by methods A and B. I account for this sample of crude gas xylene containing such a large amount of paraffins by its high boiling degrees, and I believe that if Mr. Davis had collected the fraction distilling between 136° to 141° the result would have been a higher percentage of metaxylylene and less paraffins. I beg you finally to understand that I do not claim for these methods, which I have based on O. Jacobsen's and A. Brückner's investigations, absolute scientific accuracy, but I have found them to give very satisfactory results for all practical purposes. I have converted many thousand gallons of xylene into metaxylydine, and have thus had the opportunity of practically establishing in some measure the correctness of these methods, and I hope that the communication of them may be as serviceable and valuable to members interested in this subject as they have been and yet are to myself.

\*Instead of converting these sulpho-acids into their sodium salts, it might be preferable to produce the barium salt or other salts.

## DISCUSSION.

Mr. WATSON SMITH: With regard to the valuable communication of Mr. Levinstein, I think he seems disposed to credit himself with too little. Jacobsen and Brückner had worked out certain methods for separating the isomeric xylenes, in order principally to obtain preparations, and hence merely aimed at what may be termed qualitative separation. They did not attempt to discover by what combination of means a tolerably expeditious method of quantitative separation might be built up, to be used in the estimation in mixtures of the proportionate quantities of the isomeric xylenes and paraffins present together. Mr. Levinstein, whilst pointing out that only the metaxylene is useful to the colour manufacturer, has also indicated that by means of a suitable combination of parts of the methods of Jacobsen and Brückner useful and expeditious methods of determining the quantities of the isomeric xylenes in mixture together may be found. About a week ago Mr. Levinstein placed his method in my hands, and I undertook to test its efficacy on some samples of commercial xylenes also sent me by Mr. Levinstein, which samples he had previously tested by the process. I handed the samples over to Mr. Alfred Rademacher, one of the students in the laboratory of the Owens College, and gave him the necessary directions, and he has not found the least difficulty in carrying out the method. The following are the figures obtained:—

	Meta- xylene.	Para- xylene.	Ortho- xylene.	Para- ffins.
I. Sample of xylene (1)	87	14	3	8
(2 determinations)	86½	14	3	6
II. Sample of English xylene.....	81	3	11½	1½

[Mr. Levinstein here pointed out that Sample I. corresponded to that marked L in his table, and Sample II. to E in the same table, which see.] In the estimation of the metaxylene, where the alkaline solution is distilled with wet steam, to separate the unaltered meta-isomer and paraffins from the alkaline solution of toluic acids, etc., in one experiment the volume of the naphtha was measured before steaming. It was then put back, and the mixture steamed, two Liebig's condensers, each about a yard long, being joined together to insure good condensation. The naphtha condensed was again measured. Volume before steaming = 97 c.c., and after steaming = 95 c.c.; hence but little loss was sustained in the distillation. In the treatment with sulphuric acids of different strengths it is, of course, necessary to shake repeatedly with fresh quantities of acid, in a suitable stoppered tap-funnel, until no change of the volume of the naphtha occurs after the last shaking with acid. To a certain extent the fact of the fuming acid remaining clear and colourless after the last shaking, in the estimation of paraffins, may be taken as an indication that all or nearly all the xylene is removed. When, moreover, the xylenes are thoroughly removed, and only paraffins remain, if a drop of these paraffins be allowed to fall on the back of the hand and be spread with the finger, a smell resembling that of petroleum spirit will be observed. Little more than a trace of xylenes would communicate the characteristic odour of that aromatic hydrocarbon to the paraffins. Turning now to Mr. von Hohenhausen's paper, I note that he puts the specific gravity of 90 per cent. benzol at 0.882, and Scotch 90 per cent. at 0.870. As an exceptional case I may mention that of a 90 per cent. benzol from a London gasworks, which I found to contain 6 per cent. of carbon bisulphide—the result of possibly very high carbonising temperatures on a pyritic coal. This benzol had a specific gravity of 0.900. The nauseous odour of the carbon bisulphide was completely covered and masked by the faint odour of the benzol—a somewhat

curious fact. After removing the CS<sub>2</sub> the specific gravity of the benzol became 0.880. Although the specific gravity of Scotch 90 per cent. benzol be 0.870, reduced by the presence of paraffins and other bodies of low specific gravity, yet I could understand the presence of carbon bisulphide even in such a naphtha; for the effect of the high specific gravity of this substance on the one hand might be much more than counter-balanced by the very low specific gravity of a due proportion of paraffins also present, the specific gravity of these light paraffins varying from 0.630 to 0.700 about. I presume even Scotch crude coal gas contains carbon bisulphide, and hence I hardly see how the first runnings of the benzol from the Scotch tars can escape the presence of at least some little of the bisulphide. A quick as well as a really accurate method of estimating the amount of carbon bisulphide in benzols would be a boon. I have a sample of vinic alcohol sent me by my friend Dr. Otto N. Witt, which was extracted from commercial benzene in Germany, and Dr. Witt informed me that so considerable is the amount of alcohol that its extraction as a by-product was proposed as a profitable undertaking. There were only traces of alcohol in the sample of London benzol I examined. If I were to ask any member present to smell this sample of alcohol from benzol, (it contains traces of nauseous sulphur compounds), he would be very sorry, by way of experiment, to taste a portion of it.

Mr. TRUBY: I think what Mr. Hohenhausen has said with regard to the distillation of benzol is correct, but I must take exception to some of the specific gravities mentioned by Mr. Hohenhausen. I have worked Scotch benzol of as low specific gravity as .860. In all other respects I quite agree with Mr. Hohenhausen. You can depend more on the English than on the Scotch benzol, as it gives better results. I think it would be very difficult to adulterate with bisulphide of carbon, on account of its high specific gravity and other properties. I have worked samples which contained as much as 12 per cent. nonnitriifiable products, and yet possessed a high specific gravity. I have also observed that some of the lighter boiling portions, distilling below 80°, have sometimes had a greater specific gravity than the original benzol.

Mr. DREYFUS said researches had been made and published where the separation of ortho-, para-, and meta-xylenes had been investigated by Dr. Jacobsen and Dr. Brunck, and it was of the highest importance that the users of xylol should know the proportions of the various isomeric xylenes which were contained in the commercial article. Great credit was due to Mr. Levinstein for having brought the subject before them. With regard to Mr. Hohenhausen's paper on the distillation of crude naphtha, I must say that I am rather disappointed. Mr. Hohenhausen seems to have skipped the most important part, that of the washing process previous to rectifying. I was under the impression that we should have heard of processes in the paper which were not generally known, whereas, to my great disappointment, no such new matter has been brought forward. Most of the apparatus which has been shown to us on the screen, if not all, is contained in a book published about two years ago by Dr. Schultz, of Strassburg, and there is no doubt that the apparatus described in that book would be useful to tar distillers and rectifiers of benzol. As far as the quantity of bisulphide of carbon is concerned, the same exists in large quantities in the London benzol and in less quantity in Midland benzol, whereas the Scotch benzol is quite free from it. Mr. Nickels, of London, has devised a test whereby the quantity of bisulphide of carbon contained in benzols can be ascertained. He mixes the benzol

to be tested with some caustic potash and absolute alcohol, shakes it up for a certain length of time, and allows it to stand, when xanthate of potash is formed, which separates out and can be weighed. With respect to Mr. Truby's remarks, that he found some 90 per cent. Scotch benzol to have a specific gravity of '860, I state most emphatically that I have never met with such a low specific gravity stuff, and if I had met with it I should have looked upon it as being adulterated, and not as genuine benzol. If such benzol, as stated by Mr. Truby, were submitted to nitrification in the usual way, considerably over 5 per cent. of matter would have been found that would not nitrify. The average specific gravity of the Scotch 90 per cent. that has come under my notice has been '870 to '875, and of 50 per cent. Scotch benzol '867 to '872. As far as the specific gravities of the English benzols, as given by Mr. Hohenhausen, are concerned, I think they are correct. I cannot understand the question put at the end of Mr. Hohenhausen's paper, in which he says: "What becomes of the stuff distilling between 40° and 80°, 82° and 110°, and 110° and 136° C.?" These products are not worthless, as they contain still a certain quantity of toluol and xylol, and anyone conversant with distillation will know that if such naphthas are rectified or distilled over again a further quantity of xylol is obtained.

Mr. H. GRIMSHAW: There is one aspect of the question of the increased demand for xylene, which I think is worth bringing before the notice of this meeting, as it closely affects the interests of a very large and important industry in this country and in other parts of the world. I allude to the indiarubber manufacture, in which solvent naphtha is very largely consumed. What is called solvent naphtha at one time consisted, I believe, of all those portions of the rectification of light coal-tar oils which distilled above benzol, and below about 160° C. Already for some years it has been the practice to abstract for the aniline manufacturer the toluol boiling at 110° and over, and now the demand for xylene is evidently causing the product immediately above toluol to be also abstracted. It seems to me that it will become a question for the indiarubber manufacturer to determine with exactitude what particular hydrocarbons are most valuable for the solution of indiarubber, and this subject presents, without doubt, a field for valuable and interesting research on the part of any chemist who may have the opportunity of taking it up in a scientific manner. The question of the proper solvent for an article which in the form of fine Para rubber is worth from four to five shillings per pound, and is annually imported into Liverpool alone to the value of nearly two million pounds sterling, is a very large question, and will well repay the labour devoted to it. Allusion has been made to the anomalous character of many commercial benzols of apparently correct boiling point, caused by the presence at one and the same time of carbon bisulphide and light paraffins. This is only what might be expected when we consider the fact that the boiling point of chemical substances is not at all a function of their specific gravity; that though heavy liquids do as a rule boil at a higher temperature than light ones, still there are many comparatively heavy liquids which boil at low temperatures. Carbon bisulphide, chloroform and bromine are instances of this. The naphtha adulterator is therefore in the same happy position as the milkman, who by judicious abstraction of cream and addition of water can arrange his milk to have exactly the same specific gravity as before the sophistication. Facts such as the above therefore render much more valuable such methods of determining the value of liquid products as that brought forward by the chairman, for a precise chemical method of valuation must

almost always be superior to what may be called a superficial reliance on the physical properties of boiling points, specific gravity, and so on.

Mr. GEORGE E. DAVIS: I have failed to gather from the remarks of the previous speakers what actually becomes of the intermediate products other than benzene, toluene, and xylene. It must be evident that if these products go back again and again into the still, and pure benzene, toluene, and xylene only run off, that these compounds must accumulate. These compounds, consisting as they do of paraffins and olefines, although in small quantity, may exert an injurious influence in colour manufacture. Mr. Truby has referred to the fact that some of his lighter distilling portions possessed a higher gravity than the original benzol. This may be due to the fact that the distillate was a mixture of bisulphide of carbon with substances possessing a lower boiling point than benzol, probably paraffins, and the former being in a greater proportion than exists in benzol would raise the gravity. I have been very pleased to hear Mr. Levinstein's paper upon the subject of the determination of meta-, para-, and ortho- xylene, and especially to find that there was a large quantity of orthoxylylene in the sample of xylene which I separated from coal gas. Not being an expert in these matters, I was rather troubled on receipt of a letter from Professor Armstrong stating that orthoxylylene did not usually exist in English light oils, but Mr. Levinstein has placed upon the black-board the analyses of many samples of commercial xylene in which the existence of orthoxylylene is placed beyond doubt. Mr. Grimshaw has raised a most important question relative to the future commercial value of solvent naphtha. There have been many complaints amongst the indiarubber goods manufacturers lately regarding the quality of solvent naphtha now in the market, and it seems, therefore, to point to this, that the abstraction of xylene deteriorates its quality for the manufacture of rubber goods. It is open, therefore, for chemists to either find a substitute for solvent naphtha which will serve the purposes of rubber goods manufacturers, or else tar distillers will have to leave the xylene in the solvent naphtha, as before.

#### REPLY.

The CHAIRMAN: Mr. Hohenhausen, who unfortunately cannot be present this evening, has asked me to answer, as far as I am able, any question which might be raised in reference to his paper. I must confess that I feel rather embarrassed in performing such a task, seeing this evening several of the most experienced refiners amongst us. In reference to Mr. Dreyfus's remarks, I am sorry to hear that he was disappointed with Mr. Hohenhausen's paper, but I must tell him that he is mistaken when he states that the different apparatus described by Mr. Hohenhausen may be found in Schultz's most excellent work, "*Die Chemie des Steinkohlentheers*." I certainly do not recollect that this very useful book gives a description of Vedles' two forms of apparatus for separating benzene and toluene, nor of Egrot's dephlegmator, nor of Aders' (Magdeburg) valuable refiner. Dr Schultz's book has not been translated into English, and if Mr. Hohenhausen had even taken some illustrations from this book, I fail to see, gentlemen, that such an abstraction would in any way have depreciated the merits of his paper. In reference to the washing of crude naphtha—which operation does not really come strictly within the subject of the paper—I think that Mr. Hohenhausen has in some measure explained it, but if this explanation is not satisfactory to Mr. Dreyfus, that gentleman might do great service to our Society by favouring

us at some future time with a paper on the subject which appears to him to be of so much importance. Mr. Dreyfus thinks that Mr. Truby's 90 per cent. Scotch benzene of '860 gravity must have been adulterated; but is it not possible that the difference in the temperature at which the samples were tested might to some extent account for the difference in the specific gravity? There certainly are some intermediate products in the fractions distilling between 40° to 81° C. and 111° to 134° C. which are neither benzene, toluene, nor xylene, and it would be no doubt very interesting, and valuable to find some proper use for them. I now come to my own paper, and I am glad to hear that Mr. Watson Smith obtained with my method similar results to those shown to you on the blackboard. Mr. Dreyfus, if I rightly recollect, stated that Messrs. Jacobsen and Brunck's investigations have already led them to describe methods for the separation of ortho- meta- and para- xylene, but I am not aware that Brunck has published any communication having the slightest reference to the separation of xylene. Mr. Dreyfus probably means Brückner, a chemist whom I have already mentioned in my paper—but neither he nor Jacobsen have endeavoured to found a quantitative method for determining the commercial value of crude xylene. In reference to Dr. Armstrong's communication to Mr. Davis, I am surprised to hear that the former gentleman scarcely ever found orthoxylene in English light oils. My own experience has convinced me that crude xylene, obtained from English naphtha, is never without orthoxylene. At least in the large number of samples of crude xylene which I have hitherto examined, I have always found orthoxylene to be present, and I presume that if crude xylene contains orthoxylene the latter must also have been in the light oil. In reference to the olefines, which have been mentioned, I believe by Mr. Davis, I beg to say that these hydrocarbons occur more abundantly in crude gas benzene, and also in Scotch naphtha, than in English naphtha, at least the quantity of olefines or non-saturated hydrocarbons in crude English xylene is generally very small. I quite agree with Mr. Grimshaw, and it might be interesting to him to know that solvent naphtha, after abstracting from it the xylene, is deteriorated in quality, at least as far as the rubber manufactures are concerned. I have heard of a case in point where a large quantity of solvent naphtha had been returned by a rubber manufacturer on account of the abstraction of xylene. I think that if refiners abstract the xylene from the solvent naphtha it might perhaps be advisable to replace it with toluene, and I also think that the methods described in my paper for determining the value of crude xylene might be made applicable, with a few modifications, for determining the value of solvent naphtha.

Meetings—Session 1884: March 6th, 1884.

GENERAL MEETING AT THE COLLEGE OF SCIENCE,  
NEWCASTLE, February 7th, 1884.

## ON SOME IMPROVEMENTS IN THE ESTIMATION OF TANNINS.

BY HENRY R. PROCTER, F.C.S.

Of all the methods which have been proposed for the estimation of tannins, the only one which has met with any general acceptance is that of Löwenthal, and indeed it is the only one which in rapidity of execution and constancy of results is fitted for general use. The method, as originally proposed, depends on the oxidation of the astringent solution by permanganate in presence of indigo, which not only serves as an indicator, but controls the oxidation, limiting it to those bodies which are more oxidisable than indigo. As, however, these include gallic acid and other substances which are useless to either tanner or dyer, it is necessary to remove the tannin, and by a second titration to obtain its value by difference. This Löwenthal (*Zeitschrift für Anal. Chemie*, 1877, p. 33) accomplished by a solution of gelatin and common salt, to which, after mixture with the tannin infusion, a small quantity of sulphuric or hydrochloric acid was added. It was necessary to let this stand at least some hours before a clear filtrate could be obtained, and the gelatin remaining in solution had a slight though generally negligible effect on the permanganate. In some cases, even after long standing, perfect filtration was extremely difficult and tedious, and it was also clearly proved by Simand (*Dingler's Polyt. Journal*, bd. 244, s. 400) that a certain proportion of the tanno-gelatin precipitate, varying with the acid present, and with the species of tannin, remained in solution, and thus gave too low a result. He therefore proposed to revert to the old method of separating tannin with hide raspings, or, as an improved substitute, with the gelatinous tissue of bones. This, however, though accurate when carried out with extremecare, is both a tedious and difficult process, and quite unsuited for general technical use. I have therefore tried, and I think successfully, so to modify Löwenthal's original method as to increase its accuracy, and at the same time to make it more rapid and easy of execution. I found that by saturating the clear filtrate with salt, a further precipitate containing tannin was formed, but, unfortunately, it was so finely divided that no amount of standing, or even of warming, and repeated passing through the paper, would obtain a clear filtrate. Finally, I hit on the device of mixing with the liquid, before filtration, a portion of the pure kaolin used by photographers. The effect was instantaneous and complete. A perfectly clear filtrate was obtained without any of the tedious waiting which before was necessary, and it was not only free from tannin, so far as I have been able to ascertain, but also nearly so from gelatin, so that it only gives the faintest cloudiness with tannin solution. Gelatin gives a more considerable precipitate, but this is simply due to its insolubility in the saturated salt solution, and it is redissolved on dilution with water.

I now generally work in the following manner: I employ permanganate of the strength of 1 grm. per litre and solution of the purest indigo-carmin of 5 grms. with 50 c.c. of concentrated sulphuric acid per litre, using a 25 c.c. burette and 20 c.c. of indigo solution, which consumes about 15 c.c. of permanganate. The quantity of astringent used must not require more than the remaining contents of the burette. The titration is performed in a white basin as recommended by Kathreimer, with about  $\frac{3}{4}$  litre good water, which it is best to measure approximately, so that if it con-

tains any impurity which affects the permanganate it should be constant, and thus be eliminated with the indigo. The titration is finished when the pure yellow liquid shows a faint pinkish rim. This end-reaction, which is of extraordinary delicacy, is due to Kathreiner, and is quite different to the pink caused by excess of permanganate, being an effect common to all pure yellow liquids. I do not find it needful to make the titration so slowly as has been advised—the permanganate may be dropped in rapidly, with vigorous stirring, so long as there is large excess of indigo, but as soon as the bottom of the basin can be seen through the solution it must be added very cautiously, and with occasional pauses, to allow time for its complete mixture through so large a mass of fluid. I make my infusion of such a strength that I can employ 5c.c. of the original liquid for each titration. This is repeated twice, and the results added together and denoted by *a*. I then take 50c.c. of the infusion, and add 28·6c.c. of a freshly-made solution of Nelson's gelatin of 2grms. to 100c.c. After shaking the mixture is saturated with salt, which brings the volume up to 90c.c., and 10c.c. of dilute sulphuric acid (containing 1 vol. of concentrated acid in 10) and a teaspoonful of pure kaolin are added. It is best to do this in a flask in which it can be well shaken, after which, filtration may be at once proceeded with (the flasks may be cleansed with caustic soda solution). 10c.c. of this filtrate (= 5c.c. of the original infusion) are employed for a second pair of titrations, which are added as before, and the result denoted *b*. If, further, *c*, be the quantity of permanganate required to oxidise 10c.c. of decinormal oxalic acid, and 10grms. of substance have been employed to 1 litre of infusion,  $c : (a-b) :: 6:3 : x$ , where *x* is the percentage of tannin expressed in terms of crystallised oxalic acid. For the present I invariably calculate my results in this way, since we do not actually know the relation of any single tannin to permanganate, even Neubauer's number for gallotannic acid being probably too high, and Oser's for quercitannic being only a fair approximation. It happens, moreover, that this last equivalent (62·36) does not differ from that of oxalic acid (63) more than the ordinary limits of error of such estimation, and the substitution is therefore of no commercial importance, while it is surely better to employ a standard which is easily and exactly verified than one which is certain to be modified by further research, and so to run the risk either of having our results made useless for future comparison, or of establishing a false and arbitrary equivalent. What is wanted for practical purposes is not the absolute weight of tannins in the various materials, but only a means for the relative comparison of two samples of the same material; cross comparisons of different tannins being simply delusive. If, however, it is necessary at any time to give actual percentages of gallotannic acid, it is probably best to stick to Neubauer's number for the present, as it is in general use and as likely to be correct as any other. I think when this is done the equivalent used should be definitely stated, or it will certainly lead to confusion. Neubauer's equivalent is only properly applicable to gall nuts, and possibly to sumac and myrabolans. For oak bark Oser's number or that of oxalic acid is most likely nearly correct; and this may also be approximately true of oak wood and valonia, but as respects all other materials we have no information whatever, and the oxalic equivalent is as likely to be right as any other.

I have been unable from lack of time to make so complete an examination of the results of the process with various materials as I should have liked, and as I hope to do later; but in every case in which I have

tried it, the results have been sharp and concordant, and there has been no difficulty in filtration, even with those tannins which before were most apt to give trouble. I give below a few results, not as showing the relative values of the materials, which, of course, cannot be directly compared by any analytical process, but for comparison with those obtained by other methods and modes of calculation:—

Spent Liquor .....	Tannin (as oxalic acid).		Other bodies oxidised (as oxalic acid).	
	0·12 .....	11·0 .....	0·12 .....	11·0 .....
Valonia (good Smyrna).	29·1 .....	2·3		
Sample 1 .....				
Valonia (good Smyrna).	30·7 .....	2·1		
Sample 2 .....				
Valonia (good Smyrna).	30·5 .....	1·9

Sample 2 .....				
Chestnut-wood Extract,	25·33 .....	3·68		
25° B. ....				
Pegu Cutch .....	63·30 .....	2·45		

I have proved by experiment that kaolin removes nothing which is oxidised by permanganate, but simply facilitates the precipitation and filtration; and I have often found it useful in clarifying the original infusions and liquors before the first titration. On the other hand, there is no doubt that the salt and acid of Löwenthal's method precipitate of themselves a large proportion of certain tannins. In the case of cutch this amounted to 67 per cent. of the whole. I think, however, there is good reason to believe that these bodies would also have been absorbed, or at least removed from solution by hide in the process of tanning. This is shown by the analysis of spent liquor, which originally contained the tannins of oak bark, valonia, myrabolans, gambier, hemlock, and, oak-wood extracts, etc., to the extent of 10 to 15 per cent., but which was reduced by contact with hide to 0·12 per cent. That a portion had not been absorbed but decomposed is proved by the large accumulation of oxidisable impurities (equal to 11 per cent. of oxalic acid); at the same time this example shows that the method is capable of estimating a very small portion of tannin in presence of much gallic acid and other analogous substances. It is worth remark that such spent liquors become very pale in colour, and also that the filtrates, freed from tannin by precipitation, are nearly colourless, thus proving that the colouring matters present in tanning materials are of the nature of tannins, at least as regards their precipitability by hide and gelatin.

It would be out of place here to enter upon the methods of sampling and grinding tanning materials for analysis, though I believe this to be frequently one of the most difficult parts of the process. With regard to extraction, I may mention that I have found brisk boiling in a large flask with a litre of water for half an hour to be more effective as well as less troublesome than repeated exhaustion with smaller quantities. In dissolving extracts it is well to pour them into water actually boiling, as in this way uniformity is attained, many extracts becoming permanently insoluble if mixed at first with water at too low a temperature.

## CONTRIBUTIONS TO THE DEVELOPMENT OF THE SPRENGEL AIR PUMP.

BY CHARLES H. GIMINGHAM, F.C.S.

AT the close of the year 1876 I wrote a short paper, which was published in the Proceedings of the Royal Society, on a modification of the Sprengel air pump, and showed that the slowness of the process of exhaustion, which had always been a drawback to

the employment of that air pump, might be, to a great extent overcome by the adaption described in

Fig 1

my paper. This modification is now well known, and has come into pretty general use. The result of con-

tinued experiments directed towards a similar end has been so far successful that I think I am justified in inviting for a second time the attention of the scientific public to the subject. I will now endeavour to point out, as briefly as the subject will permit, what the alterations are which I have to suggest, what results they will effect, and by what means and from what causes those results are produced; and I shall further add a few observations relating to the working of the instrument, which may be useful to those who have but small practical acquaintance with it.

The principal objects kept in view in my later efforts were those of accelerating the process of exhaustion, and of rendering that exhaustion more complete; but in addition to this it seemed to me exceedingly desirable to construct some form of jet which could be adapted in a simple way to a multiple fall tube, and before proceeding to discuss the rate of exhaustion with fall tubes of various diameters it will be well to give my reasons for adopting the par-

Fig 2

ticular form of jet that I use. From time to time various jets have been devised, mostly with the idea that the mercury should fall regularly and in long pistons down the fall tube. To my mind this is by no means necessary to the successful working of a pump, and it prevents all possibility of obtaining a rapid exhaustion. The advantages possessed by my form may be briefly stated as follows: The simple way in which it can be adapted to a multiple fall tube pump. In producing high exhaustions the great variation in the speed of the mercury flowing down the fall tubes that it affords is exceedingly useful, as it is often good at the higher exhaustions to pass the mercury through alternately slow and then fast. The mercury running slowly collects bubbles of air just below the point where the hammering takes place, and then a fast stream will generally carry them out, or far down the tube, to await the arrival of other bubbles until they are swelled sufficiently to be carried out.

Before proceeding further it will also be well to glance at and dismiss an addition to the instrument

of minor importance, but whose usefulness and simplicity of construction demand a few words of explanation. In experimenting I often found it necessary to count the number of times the mercury reservoir was raised, in order to calculate the amount of mercury passed through the pump, and for this purpose the shot counter shown on the left-hand side of the reservoir A in Fig. 1, and enlarged in Fig. 2, was constructed for automatically registering each bottle of mercury. Two tubes, *d e* and *f g* (Fig. 1), are placed at the top with an opening in it through which shot may be inserted. The shot should be picked all of one size, and just loosely fit the tubes. The lower tube is closed at the bottom and blown into a funnel

Fig. 3.

shape at the top to receive the shot as they are transferred from the upper tube, one by one, each time the reservoir A is raised. The shot being all of one size a scale may be made to indicate without counting the number of times the reservoir has been raised. The tube *f g* when filled can be removed, and the shot poured back into the opening in *d*. The arrangement for transferring the shot one at a time from the upper to the lower tube will be easily seen by reference to Fig. 2. The position that the slide carrying the reservoir A takes when raised is shown by the dotted line *a b*. It will be seen that the spring *c* will be pressed inwards, which will force, by means of the projecting piece *e*, one shot over the little brass support *f* and *e*, remaining in its new

position as long as the reservoir is raised, thus preventing the next shot from falling down. As soon, however, as the slide is lowered the spring draws *e* out, and a new shot comes down ready to be forced out the next time the slide comes up. The one I have counts to 100, which is more than I have ever required. In order to divide the mercury into smaller portions than the total contents of the bottle it is graduated at every 100 c.c., the whole contents being 800 c.c.

I shall now consider a more important branch of my subject, and ask you to follow me through a series of experiments all pointing to the conclusion that perfection of the instrument is only to be

Fig. 4.

attained by a careful regulation of diameter and length of the fall tubes employed.

It will perhaps be the more explanatory as it is the more natural plan that I should narrate the experiments in about the order in which they took place, premising that the tabular statistics appended, and to which I must often refer you, are extracted from notes carefully recorded at the time of the respective experiments.

In order to accelerate exhaustion I increased the number of fall tubes from 3 to 5, and in one pump that I used in my own laboratory for a long time, to 7. Although the results with the seven-tube pump were quite satisfactory, yet I found that for general use

a three or five tube pump was preferable. In the case of the seven fall tubes I used four of comparatively large diameter for rapidity, and three smaller ones to get the higher exhaustions not easily accomplished with fall tubes of large diameter. The rate of exhaustion with this pump was very great for one constructed on the Sprengel principle, but the supply of mercury also had to be very large, a bottle containing 800c.c. only serving for three or four minutes, which necessitated so much lifting and waste of time (the transference of the mercury from the lower reservoir into the movable one occupying almost as much time as its passage through the pump) that I afterwards used two small fixed reservoirs and transferred the mercury from the lower one to the upper by means of a small force pump, which was constructed out of a stout glass tube, using boxwood and leather for the plunger and valves. The pump could then be worked by the circulation of a few pounds of mercury, and had one sufficient work to keep a gas engine going on the force pump a great advantage would be gained. For laboratory work, however, I came to the conclusion that I had done too much in the direction of rapidity, as it will be seen further on that exhaustions cannot be reproduced

Fig. 5.

at any desired rate unless the connection between the pump and the apparatus to be exhausted is very short and open, two conditions very often impossible to obtain. To ascertain the best length and diameter for the fall tubes a single fall tube was arranged in front of my five-tube pump, a general view of which is given in Fig. 1. The single fall is not shown, as it was only temporarily arranged. It, however, was supplied from the reservoir A by making an extra joint in the glass YY-piece at *c*, and arranging a third pinch-cock there similar to *r* and *q*. The mercury passed from the reservoir through the supposed joint at *c* (Fig. 1) and two ordinary air-traps exactly similar to *h i*, which have been already described in my previous paper, but in which I have since introduced a slight improvement, consisting of a piece of twisted iron wire placed in the inner tube of the trap, which prevents the mercury forming pistons, and thus facilitates the emptying of the traps into the vacuum when it is desired to re-exhaust them. The fall tube was attached to the jet by means of a stopper which was fixed by vacuum cement.\* An arm from the upper wide part of the fall tube was connected to the five-tube pump at *l*, thus connecting the two pumps together and avoiding the necessity for separate drying tubes and measuring apparatus.

The first point—viz., the best length for the fall tubes—was decided some time back to be 39in., measured from the average height of the mercury

in the lower reservoir. This length has been arrived at from practical experience and making careful notes on the working of each pump that I have from time to time fitted up. If the fall tubes be too short the pump works very slowly, owing to the column of mercury (deducting the air spaces) not being of sufficient length to run quickly down the tube, thereby occasioning a constant filling up at the top end and consequent waste of mercury power. An experiment recorded in my note-book with a five fall tube pump whose tubes were at first made 33in. long, and then were lengthened to 39in. by sealing pieces to their lower ends, shows that by passing the same quantity of mercury through at the same rate, a certain globe was exhausted in the first case to 50mm. pressure, and in the second to 1mm., showing a great increase in the rate of exhaustion, due to the extra 6in. of fall tube. On the other hand, if they be made a greater length than 39in., the fall of the mercury at the high exhaustion causes such severe hammering that the tubes are liable to be fractured. In testing the different sized fall tubes the same length was adopted in each case, and also the same cubical contents to be exhausted. The latter was ascertained by collecting the gas at the end of the fall tube and carefully measuring it, the result being 136c.c. The first fall tube experimented with was a very wide one, in which the mercury was only just able to form pistons.

The following experiments were tried with the double object of finding the best size, and also the most economical rate for the mercury to flow through the jet. It will be seen from table 1 that it took 2,500c.c. of mercury, running at the rate of 100c.c. in 1·2 minute, to accomplish the same work that was done by 1,600c.c. of mercury running at the rate of 100c.c. in 5 minutes. On the other hand, we have the time saved by using the mercury at the quick rate, equal to 50 minutes.

This tube being too large for ordinary use, further experiments were not tried with it, except at higher exhaustions, of which I shall speak presently. It will perhaps be noticed that the exhaustions produced by the slow rate at first are less than those by the fast rate. This discrepancy is due to loss by the mercury running down the tube without properly forming pistons, owing to the large diameter of the tube. The amount of this loss will be seen by referring to the table giving the results with fall tube No. 2, which is of smaller diameter, yet we have the same

\* A mixture of beeswax and resin : 3oz. beeswax, 3oz. resin.

amount of work done by 700c.c. of mercury that it took 1,600c.c. of mercury to do with the large tube No. 1, the rate of flow and contents to be exhausted being the same in both cases.

This table also shows a gain in time by allowing the mercury to flow fast, but not bearing anything like the proportion to the amount of mercury expended which was shown with No. 1 tube. In both cases, however, extremes have been taken, and the most economical rate will be between the two experimental times taken. The experiments with No. 3 fall tube show how largely the rate of exhaustion of different pumps may vary by having differences in the diameter of the fall tubes, which from the outside would be scarcely visible.

This tube, it will be seen, took 108 mins. to produce the same exhaustion that was done in 24 mins. by the previous tube, with a far less expenditure of mercury power. In this table we have the same thing shown as in No. 1, viz., a large increase of time saved at the expense of mercury power. With this tube No. 3 an experiment was tried with the mercury running at the rate of 100c.c. in 30 mins., and producing an exhaustion of 1mm. pressure with 1,500c.c., whereas by using 1,800c.c. of mercury the same work was done in 3 hours, and 2,700c.c. accomplished the same exhaustion in 1 hour 48 mins. Although I considered this tube small, and there was a good deal of mercury

power wasted by the filling up of the top part of the fall tube, I thought it would be well to try a still smaller tube, more especially for the sake of the results at higher exhaustions.

FALL TUBE No. 4, 1.1mm. DIAMETER.

Table 4 shows the result up to 1mm. pressure. The maximum speed at which the mercury could be run with this tube was 100c.c. in 15 mins., and it will be seen that 10 hours were occupied and 4,000c.c. of mercury. This enormous increase of mercury used is caused entirely by waste, on account of the incessant filling up of the wide part of the fall tube, the direct cause of which is the friction due to the small bore of the tube.

Owing to the very limited time that I have had at my disposal for original work, I have not been able to carry out the experiments at higher exhaustions with these single fall tubes to the same detailed extent as those at the lower exhaustions. However, I have arrived at very definite conclusions with regard to the sized tubes that should be adopted for producing high exhaustions. At one time I had an idea that if a pump could be so constructed that as soon as the rarefaction had reached the barometric height by exhaustion through large fall tubes, the mercury could be turned so as to exhaust through a set of fine bore tubes, I should be able to get a high vacuum easily, because the pistons of mercury, being of small diameter, would enclose bubbles of rarefied air which would escape in a larger tube. On experimenting with pumps constructed on this principle, I soon found that I could produce as good an exhaustion with the large tubes alone as I could by using the finer ones at higher stages. It is therefore not a case of producing pistons at the higher exhaustions, the last portions of gas being taken out by a process of entanglement. The contents being exhausted remaining at 136c.c. the maximum rarefaction obtained with tube No. 4, 1.1mm. diameter, was .66M.\* with an expenditure of 7,200c.c. of mercury at 15 mins. per 100c.c. = 18 hours. Going to the other extreme I next tried tube No. 1, 2.4mm. diameter, for high exhaustions. This gave, with 2,700c.c. of mercury, an exhaustion of .1m. in 2.5 hours. In the case of fall tubes Nos. 2 and 3 I have unfortunately not recorded sufficient data to get the quantity of mercury and time occupied as in the other cases, but practically I know that with these sized tubes the high exhaustions are most readily produced, and with them I have several times recorded .01m., and three or four times with my five tube pump, which contains three tubes in the centre, of 1.5mm. diameter, and one on each side of .8mm. I have measured exhaustions up to .000006mm. equal to .008M. Such exhaustions as these are, however, only produced under the most favourable circumstances.

\* M is now generally used to stand for a millionth of an atmosphere.

## THE MEASUREMENT OF THE VACUUM.

Moderate exhaustions, viz., to within 1mm. or so of the barometric height, are generally and most readily measured by means of a barometer gauge which forms a part of every air pump. Great care is, however, necessary in reading, in order to obtain trustworthy observations at pressures within two or three millimetres of the height of the barometer. A few remarks will therefore not be out of place on the methods used to obtain the necessary precision. The position of the barometer gauge in my arrangement is shown at *u* (Fig. 1), and to facilitate comparative measurements I place on the right of it a good barometer *v* and a glass rod *w* divided into millimetres measured from the extreme lower end, which is pointed in order that contact with the surface of the mercury may be seen by the point of the rod just meeting its reflection on the bright surface of the metal. As this operation had to be repeated for every reading taken, owing to the constant and considerable variation of the height of the mercury in the gauge reservoir, I devised the following method of obviating the necessity for constantly keeping the surface of the mercury bright, as well as stooping to see that the exact contact was obtained. A stout piece of platinum wire was sealed to the lower end of the measuring rod and filed to a sharp point, from which the millimetre divisions up the rod were measured. A thin wire was attached to this platinum point, which, after being twisted into a spiral to allow of the up and down motion of the rod, proceeded to a small galvanometer, which could be placed in any convenient position on the stand of the pump. Another wire from the mercury in the gauge reservoir passes through a small battery to the other terminal of the galvanometer.

Now it is only necessary before reading the height of the gauge to lower the rod till the first movement of the galvanometer needle is seen, which shows that the surface of the mercury has been reached. I must here mention that on visiting Prof. Barrett's laboratory at Dublin, I found that he had independently devised and was using the same arrangement for one of his barometers. In the absence of a cathetometer I still use a mirror placed vertically behind the top part of the barometer and gauge, in order that the reflected image may be used to prevent errors arising from parallax. The best method of reading the difference between the heights of barometer and gauge is to have a slide running smoothly on the measuring rod, carrying a piece of clear mica with fine lines, a millimetre apart, scratched upon it, which lines must move up and down at right angles to the gauge. Even if every precaution be taken, and the finest possible adjustments be used, it is still impracticable to obtain any approach to accuracy in the measurement of exhaustion above 1mm. or so by means of the barometer gauge. We therefore have recourse to the now well-known low-tension gauge of Professor McLeod, a slight modification of which I have used in my experiments. The modification consists merely in giving it a greater range and increasing the accuracy with which it can be calibrated. In Fig. 2 is shown an ordinary gauge, of which *V* is the volume, and *P* the pressure tube. In Fig. 4 it will be seen that on the top of *V* is blown a small volume tube *v* which is about 1in. long and 5mm. internal diameter, made of a piece of thermometer tubing, with white enamel back, the latter greatly assisting one to read quickly the position of the mercury in the tube. To avoid correction for capillary depression when using the small volume tube, I have placed a second pressure tube, made of the thermometer tubing, by its side. This second pressure tube communicates with

the large pressure tube *P* at *a* and *b*, so that mercury always rises in both at the same time.

In the calibration of the McLeod gauge it has always been difficult to obtain the total contents of the bulb and volume tube—that is, to the point where the gas is enclosed by the rising mercury passing the junction of the pressure tube at *c* (Fig. 3). Professor McLeod in his original paper, recommended pouring in mercury while the apparatus was held in an inverted position, till it runs down the pressure tube. It will readily be seen by reference to Fig. 3 that this method would only give approximate results. In calibrating several gauges I have overcome the difficulty by the introduction of what is technically called an improved joint *d* (Fig. 4), which is similar to the joint forming the air-trap of a barometer, the only difference being that the inner projecting part, *e*, is very short and has a smooth round opening of 3mm. or 4mm. diameter instead of being drawn to a fine tapering point. In this case the mercury, rising upwards, cuts the communication between the bulb and the pressure tube quite sharply at the smooth aperture *c*. It will also be seen that the introduction of this joint enables one to determine accurately the contents of the bulb and volume tube to the exact point where the rising mercury encloses the amount of residual gas to be compressed. The working of the gauge is in no way altered by these slight improvements. I might therefore refer those who are not familiar with its use to Prof. McLeod's original paper in the *Phil. Mag.* for 1874; but as this is not easily accessible to all, I will briefly describe the *modus operandi*. Let it be granted that the volumetric contents *v* to *e* is accurately known, and also that from *v* to division 60 in *V*. Although in working, the values of other divisions are taken in the volumetube, these two values are sufficient for the present description. On dividing the contents of the bulb and volume tube, viz., *v* to *e*, by the contents of the volume tube *v* to *V*, we have the ratio *R* existing between the two. Now let the whole apparatus be exhausted from *g* to *h*, and then allow mercury to rise from *h* upwards, as soon as it arrives at *e* the residual gas in *f* will be cut off from the pressure tubes *P*, *p*, and gradually compressed into the volume tube by the rising mercury filling up the bulb *f*, the increase of rise in the pressure tube *P* showing the pressure in millimetres *P*<sup>1</sup> of mercury necessary to accomplish this condensation, then

$$\frac{P^1}{R}$$

gives approximately the degree of exhaustion that existed in the bulb *f* before condensation. In order to find the exact original pressure, a slight correction is necessary, on account of the depression of *P*<sup>1</sup> by the tension of the residual gas in the pump with which the gauge is connected. To apply this correction the number

$$\frac{P^1}{R}$$

must be added to *P*<sup>1</sup>, and the result again divided by *R*. The difference between the number thus obtained and the approximate pressure is, however, so slight in the high exhaustions for which the McLeod gauge is generally used, that it comes considerably within the limits of experimental errors. For example, we will take a pressure of 113mm. approximate pressure, which is represented in the particular gauge I am now mostly using by  $\frac{11}{10}$ , that is, the residual gas requires 10mm. pressure to condense it to the division 60 of the volume tube. This approximate pressure added to the 10mm. in the pressure tube equals 10+113, which, when again

divided by the ratio, viz., 88.42, in this case equals .114—that is, a difference of 1 in the third place of decimals. This, perhaps, might be considered appreciable, but as most of the pressures measured by the McLeod gauge are far lower than this, I think it will suffice to show that the correction is scarcely necessary, especially as it involves considerable extra calculation.

#### CALIBRATION OF THE GAUGE.

The calibration of the McLeod gauge has always been a matter of some little difficulty, and the method I use being to the best of my belief new, and at the same time exceedingly simple and accurate, I will give it in detail, thinking it may be useful to those who, like myself, would not trust to a gauge unless they had personally verified its calibration. Fig. 5 represents the top part of an inverted volume tube *a*, the division on it to which we want to find, from the weight of the mercury with the meniscus in position *b*, what weight of mercury would fill the space to division *a*, when we are reading with the meniscus in the dotted position *c*. Make a wooden plunger to fit rather loosely in the volume tube to be graduated, and rub the end on a piece of fine glass paper till it is perfectly flat, then place mercury in the volume tube rather above the division which it is desired to calibrate, and slowly pass the plunger down to the division. All the excess of mercury will pass the plunger, and on withdrawing the latter this excess will be removed, the exact weight of mercury to the division selected being left in the tube. In this way I proceed to obtain the values of four or five different portions of the volume tube. To correct for the meniscus when reading with it in position (Fig. 4) I have only to find the value of the annular space *d* and add it to each of the values found by the above plunger method, since the meniscus will be of the same shape in all parts of the tube. The weight of mercury that would occupy the annular space *d* is found by taking accurately the weight of mercury to a certain division with the meniscus in position *b*, and subtracting this weight from that obtained by means of the plunger to the same division. The accuracy which may be obtained by the use of a plunger in calibration is shown by the following four weights obtained while calibrating a volume tube of 4mm. internal diameter to a certain division, 115.07 grains, 115.01 grains, 115.04 grains, 115.09 grains. In calibrating a McLeod gauge, it is advisable to select three or four of the most useful divisions and accurately determine the weight of mercury for each by the method described, calculate a table for various pressures on each of these divisions, and take all observations from one or other of them. The points in an ordinary gauge with the volume tube 60mm. long, which will serve for all pressures, are (1) the topmost division, (2) 5mm., (3) 20mm., (4) 60mm.

### Birmingham and Midland Section.

MEETING, Wednesday, February 6, 1884.

### GASEOUS FUEL APPLIED TO THE HEATING OF GAS RETORTS.

BY CHAS. HUNT.

IF it were at all incumbent upon the writer of a technical paper to introduce his subject with a history of the art to which it relates that necessity does not

devolve upon me to-night; for at the last meeting of the Section our attention was largely occupied by the able survey of the rise and progress of illuminating gas with which Mr. George E. Davis appropriately ushered in his description of a proposed new departure in the economy of coal distillation. By so much, therefore, my task is a less formidable one; and if, of what remains, my subject be less generally interesting than those that have preceded it, I am not without hope that in practical importance it will compare not unfavourably with them, or indeed with any that may be brought under the notice of the Section.

Heating gas retorts by fuel in the gaseous form, as a substitute for its common application in the solid state, dates almost as far back as the introduction of the regenerative system by the late Sir William (then Dr.) Siemens, more than twenty years ago. The success that attended the latter in its applications to other industries led to its being applied experimentally in at least two gasworks in this country—namely, the Brick Lane station of the then Chartered Gas Company, and the Windsor Street works, at that time belonging to the late Birmingham Gaslight and Coke Company. In neither case, however, were the results such as to secure for it a more extended use, although, almost simultaneously, it obtained a firm and (as it proved) enduring footing at the works of the Paris Gas Company, where, with sundry modifications of detail, it has ever since been very largely employed. Here is a drawing showing substantially the arrangement which down to the year 1875 (when it was finally abandoned) was used in Birmingham for heating six beds of retorts. It is that of the familiar alternating system, with regenerators for both air and gas, worked by means of reversing valves, the producers (not shown upon the drawing) being of the ordinary kind, with sloping grate, placed at a convenient distance outside the retort-house, to which the gas was conveyed by the usual wrought-iron condensing tubes.

It is only natural to inquire how it came to pass that a system which, in its most important applications, has proved so advantageous, failed (in this country, at any rate) to displace, even in the smallest degree, the less scientific method of direct firing when applied to gas retorts. From personal experience I am able to reply that the small fuel economy and greater regularity of heating, which constituted the chief merits of the system, were too dearly purchased at the expense of simplicity, convenience, and certainty of action, the sacrifice of so much additional ground space as was required for the producers, and the employment of capital altogether disproportioned to the service performed. It may be only fair to assume that, under more favourable conditions, successive modifications might, as at the Paris Gasworks, have led to better results; but so far as the experiment (extending over several years) was pursued, the advantage remained with the more primitive system.

Other methods, however, for the attainment of the same object were, in the meantime, in process of development. It is very probable that the stimulus to further inquiry was furnished by the scarcity and consequent high prices of fuel that prevailed about ten years ago; and it may not be far wrong to conjecture that the clue to the direction which has since been followed by our German brethren with such assiduity and success was furnished by the Ponsard gas furnace—the first attempt, apparently, at continuous recuperation. I ought to qualify this observation by saying that it has special reference to recuperators built of fire-brick, because only within the last few days it has come to my knowledge that a patent was taken out as long ago as 1847, by

Richard Laming—a name well known to every student of the history of gas lighting—for a continuous recuperator made of iron tubes; and it is interesting to know that this patent describes a method of checking the primary air supply so as to generate carbonic oxide, and the introduction of a secondary air supply, upon the same lines as are now followed in the systems of regenerative firing recently introduced. It also appears that the invention was not at that time a new one, for subsequently Mr. Laming filed a disclaimer of that part of his patent, on the ground of want of novelty. It is, in fact, the adaptation of continuous recuperation that, by doing away with all necessity for valves and other compli-

were quoted, both of producer and chimney gases, showing that not only is it next to impossible, even under the most favourable conditions, to effect the entire conversion of fuel into carbonic oxide—a considerable percentage of carbonic acid being invariably present in producer gas—but also that there may be with the generator the same imperfect regulation of the air supply as with the ordinary furnace, concurrently with greatly superior economy. In addition to these, I am now enabled to refer to a series of seven analyses recently made by my colleague, Mr. Hack, at the Saltley works, which show an average of 5.2 per cent. of carbonic acid in the furnace gases, and of 9.3 per cent. of free oxygen in the chimney gases, the latter com-

SIEMENS GENERATOR (1881).

cations, has contributed more than anything else to render gas firing a practicable method for heating gas retorts. It would, of course, be idle to gainsay the advantages possessed by gaseous over solid fuel for many if not for most purposes, quite apart from the facility which it offers for economy in the recovery of waste heat; but the tendency is to overrate these, and to look upon gas firing as the principal if not the sole object to be accomplished, regardless, it would seem, of the fact that gasifying has to be resorted to, in connection with the regenerative system, as a means to the end, rather than as the end in view. In thus repeating an opinion expressed in the paper read by myself before the Midland Association of Gas Managers, in September, 1882,\* I am enabled to adduce further evidence in confirmation of its accuracy. In the course of that paper some analyses

paring with 9.7 per cent. in the case of an ordinary furnace, in which the consumption of fuel was nearly one-half as much again as in the regenerative furnaces. The latter, it is clear, owed little, if any, of their superiority to better regulation of the air supply.

The invariable presence of carbonic acid in producer gases—indicating to that extent complete combustion—points to the desirability of placing the generator in as close proximity as possible to the furnace, so as to avoid loss of heat in transmission. Nevertheless, the use of detached generators, in the large majority of its applications, goes far to prove that the economy of gas firing is independent of any moderate degree of imperfect gasification; nor is it conceivable that this can be due to any other cause than the recovery, more or less complete, of the waste heat. It is, however, objected by some that gasification alone is productive of the fullest economy, and

\* See *Journal of Gas Lighting*, vol. XL, p. 598.

ought consequently to be pursued as the object of primary importance.

With the view of determining this question, a Siemens producer (see diagram) was placed in a suitable position outside of a retort-house at the Windsor Street

works, and the gas from it conveyed through an iron conduit lined with fire-brick, and provided with suitable branches, to two beds of retorts. No change was made in the construction of the latter, beyond closing up the space below the fire-bars, so as to

cation of the Wilson gas, Mr. Allhusen says: "We began by using cold air, which was a failure; then heating the air through metal pipes, which was an improvement; and now we have at last reached perfection by the adoption of a series of hot-air stoves, by means of which the air is forced into the combustion chambers at a temperature of about 1,000° Fahr."

Much attention has lately been attracted to the apparatus devised by Mr. Sutherland, and just referred to, for gasifying fuel under exhaust, so as to increase the generating capacity of the producer, and for extracting the tar and ammonia from the resultant gases. A word concerning it, in passing, may not, therefore, be considered out of place. It is hardly to be expected that gas manufacturers should regard with perfect equanimity the development of new sources for the production, in quantities sufficiently large to affect the market, of two of their most valuable by-products; but it may reasonably be doubted whether the effort of Mr. Sutherland is destined to have any appreciable effect in this direction. It is almost needless to observe, since the fact is now generally recognised, that tar which is produced under a condition of either partial or complete oxidation of the fuel is of a different character from that which is the result of distillation in closed vessels, conducted at moderately high temperatures, benzene being conspicuously absent and its place supplied by the comparatively

SIEMENS REGENERATOR FURNACE, AS FORMERLY APPLIED AT THE WINDSOR STREET GASWORKS, BIRMINGHAM

prevent ingress of air in that direction, and bring the necessary supply more completely under control. The gas was introduced at either side through openings made for the purpose in the furnace doors, the same means being employed for the admission of air, which was regulated as nearly as practicable to the requirements of combustion, as indicated by analyses made from time to time of the chimney gases. Periodical analyses were also made of the gases issuing from the producer, these showing the action of the latter to be satisfactory. The results obtained were a much lower heat in the retort beds than with the usual system of firing, and a great increase in the quantity of fuel used, the actual consumption being 6 cwt. of coke and slack per ton of coals carbonised, as against 3.53 cwt. of coke with direct firing, or a difference in favour of the latter of no less than 70 per cent. Almost simultaneously a similar experiment was in progress with Sutherland's apparatus, with analogous results. In both instances it was proved beyond question that, for heating gas retorts, gasification without recuperation was a step in the wrong direction. This experience has been curiously confirmed in connection with the application of gaseous fuel to another industry—that of salt-cake manufacture—by Mr. Allhusen, of the Newcastle Chemical Works, quoted by Mr. Wilson in the paper read by him at the first meeting of this section.\* Speaking of his appli-

valueless paraffin oil. It also appears probable that the same cause—viz., the admission of air, which thus operates so adversely—tends at the same time to limit the available production of ammonia, for this is yielded in much smaller quantity than usually obtains in the manufacture of illuminating gas, under conditions, as regards temperature, not unfavourable to its formation.\* The sum realisable per ton of coals by these products, tar and ammonia, has not yet, so far as I am aware, been determined upon sufficiently reliable data, but it cannot be considerable, while the cost of securing it, as represented by the loss of heat involved in the process, and the expenditure upon plant, is by no means insignificant. Speaking from actual experience, the latter amounts to at least five times as much per ton of coals as is found to be sufficient in the manufacture of illuminating gas for corresponding plant of greater efficiency; while, as regards the former, the cooling down of so large a volume of gases representing each ton of coals gasified, assuming this to be from 150,000 to 180,000 cubic feet, from a temperature of, say, 1,000° Fahr. to that which is necessary for the elimination of ammonia, about 60° Fahr., will be found upon calculation to represent something like 10 per cent. of the weight of the coal operated upon. Together, these two items make a formidable inroad into the saving to be effected by

\* See *Journal of Gas Lighting*, vol. xliii., page 231.

\* This was written previous to the publication of Mr. Watson Smith's paper, read before the Liverpool Section of the Society of Chemical Industry, December 5, 1883.

the extraction and sale of the by-products, to say nothing of the additional space required for the apparatus and the increased attention which it entails.

At first the new system of gas firing was applied to gas retorts with a very small amount of recuperation. It was, of course, necessary to introduce a secondary air supply, and the way to do this naturally suggested itself in the form of a longitudinal flue placed on each side of the furnace or gas flue, and extending almost to the back of the retort bed. These, being open at the front for the admission of air, fed combustion by means of openings placed at intervals throughout their entire length. When space permitted, two or more such flues were constructed lower down in the setting, air being admitted into the bottom one, and made to traverse backwards and forwards, always in the opposite direction to the waste gases, until it reached the top or distributing flue. Gradually more elaboration was introduced, until, in its best known

late Sir W. Siemens, being upon the same principle. Drs. Schilling and Bunte have adopted a grate generator, having fire-bars arranged very much after the manner of an ordinary furnace. The two last named are examples of detached generators. In addition to these three there is a fourth, which although regarded with less favour by the leading engineers of Germany, where it originated, has won approval in this country by its superior adaptability. This is known as the Klönne, a trial of which, two years ago, at the Adderley Street works, Birmingham, led to its adoption upon a larger scale at the Windsor Street and Saltley works, and was largely instrumental in causing its introduction in other places. At the present time it and the new Siemens system, already mentioned, may be said practically to divide the attention of English gas-makers on this subject, although other methods have been or are in course of being tried, and I shall have to refer to a recent modification of my own devising.

VALON'S GENERATOR FURNACE.

and most approved types, the modern regenerative furnace has assumed dimensions which, on first thought, appear to be out of all proportion to the work required of it, but to which the English gas-maker is fast becoming reconciled by the advantages it is found to possess.

Of the many systems that are now in use in Germany, it may be correct to describe as the principal ones the following—namely, the Liegel, the Dessau or Didier, and one devised by Drs. Schilling and Bunte, of Munich. In the first of these, which has what is termed a "slit" generator—*i.e.*, a generator terminating in a long narrow slit for the admission of the primary air supply—may be recognised the prototype of the first generator furnace constructed in England, at the Old Kent Road Gasworks, by the then engineer (Mr. G. Livesey), and since improved by Mr. W. A. Valon, of Ramsgate. The second has a hearth generator, and this also is represented in this country; the producer in use at the Glasgow Gasworks, which originated with the

The Siemens system, as applied by Mr. W. Foulis, chief engineer to the Glasgow Corporation Gas Department, was fully described by him at the last meeting of the Gas Institute, held at Sheffield;\* and, briefly, it may be said to comprise a generator, or producer, placed outside the retort bed, formed by a wrought-iron casing lined with fire-brick, and having openings at the bottom, three or four in number, for promoting combustion. The fuel is deposited upon a hearth of fire-brick, there being no fire-bars, and at each opening a small jet of steam is applied, with the object of preventing the formation of clinker. A gas flue connects the producer with the setting, and is made continuous through the latter, the gas being thus made to meet the heated air issuing from the regenerator. This latter possesses one merit to perfection, that of extreme simplicity, the alternating gas and air flues being formed with ordinary fire-bricks and tiles. The producer is filled

\* See *Journal of Gas Lighting*, vol. xli., p. 1139.

periodically with coke hot from the retorts, and requires no other attention than the removal of ashes and clinker from the hearth previous to being filled up with fresh fuel. Mr. Foulis thus describes the advantages of the system, which he has already applied to 900 retorts:—

"A considerable saving in labour in firing; a decrease in the quantity of fuel used; an increase in the quantity of gas produced per mouthpiece; and greater durability of the retorts and settings. The saving in labour will be at once apparent. There is no firing, in the ordinary sense, and no clinkering. The saving in fuel we find to be considerable. As has already been pointed out the coke we use is very inferior, and consequently a much larger percentage is required to heat the retorts than when a better coke is employed. In ordinary furnace-heating we find it requires about 60 per cent. of the coke made to maintain the heats; with the regenerative furnace 33 per cent. is found to be sufficient, and we have a surplus of heat. The retorts are 13in. by 18in. and 9ft.

however opinions may differ as to the comparative merits of particular systems. As showing how very divergent these are may be cited that of Mr. W. A. Valon, of the Ramsgate Gasworks,\* who has applied a much less costly and pretentious arrangement, with, according to his view, equally good results. With Mr. Valon's efforts in this direction it is impossible not to sympathise, and it is certain that all who are interested in the development of regenerative firing will wish him further success; but, in the meantime, it must be admitted that his system has yet to be proved by comparison with others under different conditions than those existing at his own works.

The Klönne system has been applied very extensively at the Saltley works, and early last year was applied to 126 retorts at the Windsor Street works,

KLÖNNE'S REGENERATIVE FURNACE.

KLÖNNE'S REGENERATIVE FURNACE AS APPLIED AT WINDSOR STREET GASWORKS, BIRMINGHAM.

long, and they are charged every three hours. The production per retort—with ordinary furnace-heating, and with coals yielding barely 10,000 cubic feet per ton—is about 7,000 cubic feet in 24 hours. With the regenerative furnaces we get from 8,000 to 8,500 cubic feet in the same time. There is no dust or deposit of any kind on the outside of the retorts or in the setting, the brickwork after six months' work being as clean as when it was put up. The heats are very uniform, and are much less dependent on the firemen than with the old system. At present we have a producer to each setting of eight retorts. We have had, however, at work for some months a producer supplying the retorts on both sides of the bench. This plan is working well, and all the settings we are now erecting are built so that a similar arrangement can be carried out. In this case the regenerators, etc., remain as before; but the gas flue is carried right through from one side to the other. When one producer is used for both sides of the bench the fuel needed is only 25 per cent. Takirg the quality of the coke into consideration this is a remarkably low percentage."

This unequivocal testimony in favour of regenerative firing does not want for abundant confirmation,

the plan of construction being essentially the same as had been previously followed at Adderley Street, with the addition of a provision for heating the primary air supply. On referring to the diagram it will be seen that the generator stands partly forward—about 2ft. 5in.—from the setting, being by this much a departure from the original conception of Mr. Klönne. This was arranged, at my suggestion, to facilitate the charging with hot coke direct from the retorts. The generator very closely resembles the first Siemens producer, having fire-bars in front, forming a succession of steps, immediately above the top one of which, and protected from the fire by a projecting row of fire-clay lumps, is placed

\* See *Journal of Gas Lighting*, vol. xli., pp. 269-70.

a shallow water pan. Water being continually fed to this pan overflows, falling from bar to bar into the ash-pan below. An air-tight or closely-fitting door, with adjustable ports, furnishes the means of controlling the primary air supply; and in addition side channels are formed, leading from the front to the under side of the fire-bars, by which means a certain amount of recuperation is effected. On issuing from the generator the combustible gases enter the setting through the openings at the top of the arch, and meet the heated air from the recuperators. These are formed of a series of special bricks, a specimen of which is on the table, having openings, in one direction for the downward current of waste gases, and in another (at right angles to the former) for the passage of the air,

Some inconvenience has been experienced with these settings, from the unequal distribution of this intense heat, by far the largest share falling to the bottom middle retort, which, in consequence, soon became a source of much embarrassment, and had to be removed. Where the system has been applied to settings having the same arrangement of retorts as is usual with direct firing, this difficulty has not been felt to anything like the same extent, the reason being that in these there is always a space corresponding with that occupied by the furnace, serving in a great measure to disperse the heat before it reaches the retorts. In other respects the system has fully answered expectations, the furnaces being easy to manage, the clinkering being done once in 24 hours (while at Saltley and elsewhere it is done only once in

SIEMENS GENERATOR, AS USED IN GLASGOW.

DESSAU OR DIDIER GENERATOR, AS USED IN DRESDEN.

which, introduced at the bottom of the setting, threads its way first to the right and then to the left, upwards, until it reaches the top highly heated. There is thus a constantly descending current of waste heat, divided only by a very thin partition of fire-brick—the thickness of material being only  $1\frac{1}{2}$  in.—from an equally constant ascending current of air, the conduction of heat being, under these conditions, almost as complete as is practically possible. The effect of this recuperation is to produce an exceedingly high temperature of combustion—so high, in fact, as to melt fire-bricks of the very best quality when brought within its immediate influence, and necessitating the greatest care in the disposal of the brickwork, so as to avoid undue exposure of any portion of it.

48 hours), and the fuel used has been found, by repeated measurement, not to exceed from 14 to 15 per cent. of the coke produced. This is only a little more than one-half the consumption by the old method, although it would not be fair to attribute the whole of it to regenerative firing, because the comparison in this case has been between settings of unequal capacity—namely, sevens by the old method and nines by the new—economy almost invariably being found to result from the heating of a larger number of retorts from the same source. Making, however, all due allowance for this, there still remains a very large margin—amounting probably to 33 per cent.—to be credited to the recovery of the waste heat. Nor do the advantages of regenerative firing end here. The temperature of

the retorts is maintained with greater regularity, there being no loss of heat in clinking, as in the old method, and is more under control, it being possible, by a slight alteration of the dampers, to vary it to almost any extent in the course of a very few hours, thus placing within easy reach the means of very considerably increasing their productiveness, without the necessity for a more than proportionate expenditure of fuel. It would be impossible to say this of the old method of firing, in which high heats, although by no means the invariable accompaniment, are seldom or never attained without a lavish expenditure of fuel. The reason for this is to be found in the fact that the waste heat necessarily leaves the setting at or near to the temperature of the last retort, so that the more this is augmented the greater, by the old method, must be the loss, whereas by the use of regenerators of sufficient capacity a very large proportion is restored to the furnace. How great is the margin for saving in this direction may be learned, not alone from actual experience but also from calculation. A French writer upon this subject (M. Melon), in a paper\* read by him in 1881 before the Société Technique de l'Industrie du Gaz en France, thus classifies the sources of loss of heat from a retort setting:—

- (a) Loss by the chimney.
- (b) Loss by radiation from the front.
- (c) Loss by radiation from the foundations, etc.
- (d) Loss by the escape of distilled gases.
- (e) Loss in the furnace, by the formation of water and clinker.
- (f) Sundry losses, due to the opening of the furnace for clinking, the opening of the retorts during drawing and charging, etc.

And his summary is as follows:—

	Per cent.
Loss by the chimney .....	60.0
Loss by the products .....	17.0
Loss by the casing .....	2.5
Loss by the radiation .....	1.5
Loss by the furnaces .....	2.5
Sundry losses (estimated) .....	5.5

89.0

Leaving 11 per cent. as the proportion actually realised in carbonisation.

These estimates are based upon the assumption that the gases leave the setting at a temperature of about 2,200° Fahr., and are therefore evidently intended to apply to the employment of high heats. Where, as is most usual with us, the retorts are worked at six-hour charges, the temperature of the escaping gases does not probably exceed from 1,600° to 1,800° Fahr., and the loss by the chimney is consequently less. The figures, however, afford a sufficiently clear indication of the enormous loss simply inevitable under the old system, more than one-half of which is already in course of being arrested by the introduction of continuous recuperation. Whether more than this is possible remains to be seen, although a further reduction appears highly probable, from the fact that the escaping gases still leave the settings at a temperature varying from 600° to 900° Fahr., which is much more than sufficient for the maintenance of the necessary chimney draught. The cost of the regenerative portion alone of these settings of nines amounted to about £7 per mouthpiece, which is more than had been anticipated, and greater, in my opinion, than should be needful for the purpose. Being doubtful also of the effect of the arrangement for distributing the heat (which subsequent experience proved to be fully justified), I had, previous to the completion of the settings, devised a modification, constituting an entirely new recuperator, although proceeding upon the same lines, with a view of meeting, at any rate in some measure, both these objections. I hoped to have been able to lay before

the members the details of this arrangement, but as the latter may become the subject of a patent, I am advised that it will not be desirable to do so. I will therefore content myself with saying that in its effect, local heating, if not entirely avoided, is, at all events, less pronounced than in the Klönne setting; the consumption of fuel is no greater, being 1½ per cent. of the coke produced; while in the cost of construction there is a saving in material and labour of rather more than £20 per bed. Other improvements are now contemplated, by which it is confidently anticipated that further economy in cost of construction will be realised, involving a still more complete departure from the original system. The generator has also, in my arrangement, undergone considerable alteration, being brought out farther from the setting, and built up square at the back, so as to admit of its being filled up more easily. The charging-door, also, is placed in a horizontal position, this being found more convenient than the angular one imposed by Mr. Klönne. In this I find I have been anticipated by MM. R. Radot and A. Lencauchez, whose arrangement, as used at the Bordeaux Gasworks, will be found illustrated in the current volume of the Transactions of the Société Technique de l'Industrie du Gaz en France.

In the first application of any new system, difficulties have almost inevitably to be encountered. Whoever has not met with them with regenerative firing has something yet to learn. Speaking for myself, they have led me to take a keener interest in the subject than perhaps under easier conditions I should have found convenient, and have forced me to try conclusions that otherwise I might have avoided. It has been shown me, for example, that it is one thing to produce an exceedingly high initial temperature and another to apply it without inconvenience throughout the setting. The former is comparatively easy, there being many more ways than one of constructing an efficient, continuous recuperator; but the latter, while more difficult, is an absolute necessity for comfortable and economical working. The saving of a few pounds of fuel may be dearly purchased at the cost of a superabundance of stopped ascension-pipes and pitch in the hydraulic mains, to say nothing of injury to the brickwork of the settings. Local heating is a fruitful source of all these evils, and requires to be guarded against with the utmost care. For its avoidance a sufficient space should in all cases be provided to admit of the dispersion of the heat before it reaches the first retorts; and it will be found that where the centre flues have a width between the retorts of not more than eight inches, or where there is no space corresponding with the furnace of an ordinary setting, the plan adopted by Mr. Foulis—of a two-chambered setting, in which the heat is made to rise through all the flues in the front, and descend through all the flues in the back or central chamber—is to be preferred to the more usual one, by which the heat passes up the centre of the setting, over the top retorts, and down by the outer flues. Great evenness of heating is in this way insured; and for the rest, those who incline to working at high heats and short charges must depend, for the avoidance of stopped pipes, upon a light water-seal secured by the removal of the tar from the hydraulic main as rapidly as it is deposited. Another point of importance for the prevention of injury to the brickwork or retorts from the excessive temperature at the point of combustion is the formation, in its immediate locality, of a continuous open chamber, in which the first intensity may spend itself, as it were, before coming into contact with the brickwork. Attention to these matters of detail will be fully repaid; and a little skill brought to bear in the

\* See *Journal of Gas Lighting*, vol. xxxviii., p. 423.

construction of the settings will be found more to the purpose than a search, prosecuted to the ends of the earth, after the best fire-resisting material.

In the construction of a recuperator, certain conditions are necessary to be observed. These are the employment of the thinnest possible material consistent with strength and durability, and the securing of long contact, both for air and waste heat. When at Munich a few years ago, I remarked to Dr. Schilling, who was then experimenting with his regenerative furnace, upon the labyrinth of passages through which the air was made to travel by his arrangement, observing that it appeared unnecessary. He replied that it was a mistake to suppose that air could be raised to a high temperature otherwise than by long contact with a heated surface; and so it has proved in our experience. Not only does the air, in its passage upward take the shortest way, but also the waste heat in its passage downwards, if the draught be at all keen; and therefore the recuperator should be constructed with a view to the longest practicable retention in both cases. Since, also, the absorption of heat by the air is dependent upon conduction through the material employed, it follows that the thinner the medium the more rapid must be the effect. When the recuperator is constructed of material of the average thickness—say  $2\frac{1}{2}$  or 3 in.—very much greater space must be needed to secure the same degree of efficiency.

As to which is the best form of producer, opinions differ, and will probably continue to differ. When there is sufficient depth available to admit of the clinkering being done from below, the slit generator offers the advantage of simplicity; but whether it is equally suitable for all kinds of gas coke is doubtful, since experience seems divided upon the point. Nor does it appear at all possible, unless the setting be of considerable width, to apply it in connection with the most approved forms of recuperators; while the inevitable radiation from the walls and arch of the tunnel affording access to the under side of the generator must be a source of considerable loss. Otherwise, as a matter of economy no less than of convenience, there can be little doubt that the generator is in its proper place when forming a part of the construction of the setting, instead of, as in some systems, detached from it. This conclusion is inevitable to those who, like myself, have had an opportunity of comparing the two systems of construction side by side. Radiation from the enclosed generator may be almost entirely prevented, and is so inappreciable as to be almost imperceptible; whereas, on the other hand, from the detached generator—the Siemens, for example—it is most painfully evident. In cost of attendance, also, according to my experience, the latter compares unfavourably with the enclosed generator.

Depth of fuel has generally been considered essential to gasification, although the analyses published by Mr. Foulis show that conversion to carbonic oxide is, if anything, more complete when the fire has burnt low, than after it has been freshly charged. My own observations confirm this, and lead me to say that in all respects the dimensions of a generator should be determined solely from considerations of general convenience. A shallow fire requires replenishing more often than a deep one, and that is practically all the difference between the two; while a fire having a large area of grate surface will last longer without clinkering than one with a lesser area. Having tried several kinds, I have come to the conclusion that the advantage of a long interval without clinkering is more apparent than real; and that greater regularity of heating is secured by a comparatively narrow grate, clinkered once every twelve hours, than by a very wide one which is allowed to run twice or even

four times as long without being clinkered. Local circumstances, however, must largely decide both the dimensions and form of the generator to be employed; but, in any case, it is desirable to effect control of the air supply by means of a tolerably close-fitting door, furnished with adjustable ports similar to the furnace doors of Cornish or Lancashire boilers.

Although for the most part my observations have been necessarily addressed to a somewhat limited audience, composed of my professional brethren, I am anxious not to conclude without making some attempt at showing that the subject, far from being of a special nature, interesting only to gas makers, is really susceptible of very much wider treatment. It has been explained that, in addition to other advantages derived from continuous recuperation as applied to gas-retorts, not the least considerable is the saving in fuel, varying, according to the efficiency of the system, from 20 to upwards of 40 per cent. Speaking roundly, this means that for every ton of coals used in the production of illuminating gas, an additional hundredweight of coke is rendered available for other purposes. What this may amount to in a comparatively short space of time it is not difficult to estimate. In Birmingham alone it is not improbable that within the next few years the annual output of coke will, from this source, be increased by from 12,000 to 15,000 tons; while the yearly consumption of coals for gas-making purposes throughout the kingdom suggests a possible addition to our fuel resources of from 300,000 to 400,000 tons of coke per annum. This ought to be nothing short of a national benefit, although directly affecting only one particular class—namely, the consumers of gas; who, whether supplied by companies or by corporation, derive, with few exceptions, the full advantage of all reductions in the cost of manufacture. It may not, however, be at all safe to assume a money advantage corresponding with this enormous saving—for enormous it is—since even at the present time, it is only too evident that, notwithstanding its smokeless character and consequent adaptability to many requirements, gas coke does not command that full appreciation which its merits certainly deserve. This observation is much less applicable to Birmingham and its vicinity than to other localities that shall be nameless, whence relief from heavy stocks is habitually sought by appeals to distant markets; nevertheless, it is apparent that even here, in this great centre of manufacture, with its huge importations of fuel, gas coke occupies a far less prominent position than is its due. Why this should be so it is not within the scope of this paper to attempt to determine; but as a kind of natural sequence to the subject we have been considering it falls to me to direct attention to a very wide field for the employment of gas coke, hitherto all but absolutely unexplored.

A separate service of heating gas has long been a favourite idea of men in the highest walks of science; and at 1s. per 1,000 cubic feet, or thereabouts, has almost come to be looked upon as one of the greatest boons the future can possibly have in store for us. It is, however, generally forgotten that gas at such a price, or even at 6d. per 1,000 cubic feet, might still be relatively dear, in consequence of its low calorific value; the fact being that the very best heating gas that has

been proposed for distribution has offered no more favourable comparison with ordinary illuminating gas than as 3 or perhaps  $2\frac{1}{2}$  to 1. Its use could not, therefore, pay as against the latter at the price charged (say) in Birmingham or other large towns. But while the argument in its favour is thus altogether inconclusive, it is not equally clear that the instinct which has prompted the demand is erroneous or unsound. On the contrary, there is evidence enough to show that in every manufacturing district, and possibly for domestic purposes also, a really low-priced heating gas would be largely patronised. The question is how it may be best obtained, by an extension of the system of illuminating gas, or by an entirely new departure? As regards the former, the gradual diminution in the cost of manufacture is tending to bring illuminating gas into very general request for heating purposes; and this it has been proposed to further encourage by the rather doubtful expedient of differential rates. At the same time it has been repeatedly shown that the establishment of separate fuel-works would stand no chance of success in competition with the existing gas system, which, at a comparatively small cost, is susceptible of development to any reasonable extent; and therefore in this direction it has become the custom to seek for a solution of the problem.

Quite recently an important contribution has been made to the subject by the *Journal of Gas Lighting*, in commenting upon a letter from a correspondent who, writing under the *nom de plume* of "Progress," advocates the conversion, at gasworks, of coke into water gas, for distribution at a cheap rate. It has been remarked in the editorial columns that the consummation wished for by "Progress" may be much nearer than he imagines, inasmuch as the rapid extension of the generator system is furnishing, to those who may choose to apply them, the means of gasifying all surplus coke at a minimum of cost, and without the necessity of any material alteration or interference with the present system. I believe this to be one of the most reasonable suggestions on the subject that has yet been offered; and if ever a separate supply of fuel gas becomes a reality, it should be by such a method. Having devoted to generator firing a considerable amount of attention, I am disposed to say further that, given a real demand for a rough heating gas, there are no insurmountable difficulties in the way of supplying it in the manner proposed, and at a very moderate cost, as compared with what would be incurred by the establishment of separate works. In a stage house the requisite space is already provided. The saving of heat by filling the generators direct from the retorts would largely compensate for the loss involved in gasifying and in the subsequent cooling of the gases; while there would be an additional set-off in the almost entire absence of manual labour and waste in handling the coke. There seems to be really no reason why, if desired, the whole of the coke should not leave the retort-house in the form of combustible gases, ready, after cooling, for distribution in the ordinary way. Whether, on a balance of considerations, this would be economically desirable, is too wide a question to enter upon at the present moment; but it may be at once pointed out that not a little of the commercial success of such an undertaking must depend upon the means available for the application of the gas. Experience has shown that for many purposes even the heating power of illuminating gas is insufficient; and we also know that the application of carbonic oxide, or water gas, is by no means uniformly successful when combustion is promoted by cold air. From this it may be fairly inferred that the difficulties to be met with in the introduction of a purely heating gas are by no means inconsiderable, although

perhaps not so formidable as to absolutely forbid the enterprise. In the meantime, however, why should not heat users avail themselves of the means which are already at their command for securing all the advantages that can possibly be derived from gaseous fuel when a high temperature is necessary.

The earliest attempts at recuperation were by means of what is now called the primary air supply; and only when this was found to be unworkable—doubtless owing, in a great measure, to the overheating of the fire-bars—does it appear that recourse was had to conversion of the fuel into combustible gases. This was the great step that led to success, although accompanied by the separation of the producer from the furnace, and the consequent cooling down of the gases in their passage from the one to the other. The gases, however, thus became an additional vehicle for the recovery of waste heat, rendering the familiar two-chambered recuperator an inseparable part of the system. Of the great original conception of the brothers Siemens it would be superfluous to speak in terms of even the highest admiration, because the immense benefits it has conferred upon the manufacturing industries of this and other countries are universally acknowledged. But in the application of a principle there can be no such thing as finality, and it is only natural that efforts should be continually directed to simplifying the means by which the desired effect may be secured. Notably the periodical clogging up of the different parts of the apparatus with carbonaceous matter, apparently inseparable from the use of raw coal, has given exercise to much ingenuity. It gave the first impulse to the invention of Mr. Sutherland, and not improbably to others also, which have the same object in view, although proceeding upon entirely different lines.

But must it not be said that recuperation is still beyond the reach of all but the large capitalist, or resorted to only for special purposes, requiring the maintenance of an exceptionally high temperature irrespective of other considerations? At all events, it is certain that its use is confined to a comparatively few industries, notwithstanding that the scope for its employment is practically limitless. On the other hand, may it not be suggested, with very good reason, that in one or other of the systems of continuous recuperation now in course of introduction will be found a thoroughly reliable, comparatively inexpensive, and most manageable substitute for the alternating system, without the loss of any of its recognized advantages? It may be objected to this that I am advocating, in the interests of one particular manufacture—that of illuminating gas—the use of gas coke in place of raw coal; but I do so in the general interest no less than in the interest of the consumer of the fuel, who would be advantaged by the change, even though he might have to pay a somewhat higher price for the substitute. Already continuous recuperation is, I am informed, in course of introduction in connection with the Simon-Carves coke oven and Hislop's process for the recovery of lime; and it is to be hoped that manufacturers in this district will not be behindhand in showing what may be done in this direction by very simple means.

In the application of the original Siemens system of regenerative firing at Windsor Street, the fuel expenditure (slack being used) was 3·4 cwt. per ton of coal carbonised, against 4 cwt. of the same fuel required with direct firing. With coke as the fuel, the consumption by the latter method has averaged rather more than 3½ cwt. per ton of coal carbonised; whereas by gas firing with continuous recuperation it has been proved possible to effect the same work with 2 cwt. Should not this be an incentive to other heat users to do likewise?

## DISCUSSION.

Mr. G. E. STEVENSON : Mr. Chairman, I think, sir, it is very kind of you to invite a stranger, who is not a member of this Society, to take part in a discussion here, and I thank you for doing me the honour, and us generally, as gas engineers, of inviting us to speak here to-night. The subject of regenerative furnaces is one which has interested me, I may say, for several years, and one to which I have devoted considerable attention, though it has not been my lot to make practical experiments with the principle to any great extent. I may say my attention was directed to this subject, in the first place, by seeing in Germany the earlier attempts that were made by engineers to apply regenerative furnaces for the heating of gas retorts. It may not, perhaps, be known to all present here that German gas manufacturers have always been in the habit of heating their retorts to a much higher temperature than we in England, their custom being to make their retorts yield a larger quantity of gas in 24 hours than we have been in the habit of doing. One reason, perhaps, is the illuminating power is not so high as that which is required by the legislation with regard to our own gas supply, and therefore they were enabled to get a greater yield of gas out of the coal. I may say that when I first returned from Germany I began to mention this subject to my friends and colleagues, and I think I may take credit myself of contributing towards creating an interest in this subject. In Birmingham it was my privilege to read a paper introducing drawings of the Liegel furnaces used at Frankfurt and elsewhere before the Association of Midland Gas Engineers, and from that time Mr. Hunt took the subject up with success. We have to-day seen the furnaces at Windsor Street and Saltley, and the style he has changed his furnaces to is a more economical one; and as Mr. Hunt has told us, there are now thousands of tons of coke saved in a year which were formerly used in heating retorts. There are one or two points in Mr. Hunt's paper to which I should like to refer. I was rather surprised to see in the table of analyses taken from the Saltley furnaces, that so large a portion of oxygen was present in the waste gases; and as the amount is about the same as that present in ordinary furnaces, it appears to lead Mr. Hunt to conclude that apart from regeneration there is no advantage in gas-heating furnaces. I cannot say that I come to that conclusion. The reason that large quantities of oxygen are found in the exit gases may be due to the imperfect air-tightness of the regenerating flues; and if that be so the air that produces the oxygen has entered the setting of retorts after the heated gases have done their work and has no influence on combustion, so as to lower the temperature of the retorts. My opinion about the matter is that gas-heating furnaces are decidedly superior to ordinary furnaces. I think that regeneration is a great additional saving, but where it becomes very elaborate in construction it is a question in the minds of all whether the construction pays for the saving effected. The matter has hardly yet been worked out. There was also a question about the dispersion of the heat in the settings. Mr. Hunt stated that although it was easy to create an intense heat it was rather difficult to obtain a proper dispersion of that heat, so that the whole of the retorts and brickwork should be heated to a uniform temperature. The principle to be aimed at is that combustion of the carbonic oxide gas should take place slowly, and not all at once. In the earlier forms of furnaces, such as that used by Mr. Valon, the air supply is delivered into the furnaces in a large volume, and in that case a

very intense combustion takes place. The heated gases, after combustion, pass through the retort setting in the usual way, and a very intense initial heat is created, which decreases as the gases pass in and come in contact with the retorts. If the air is mixed with the carbonic oxide in small quantities, the combustion takes place gradually throughout the whole length of the setting, and it is then possible to obtain a slower combustion, so that by the time the waste gases reach the exit flue, and are leaving the retorts, combustion ends. Of course it is difficult to heat air to a high temperature without keeping it a very long time in contact with the heated surfaces of the material by which it is to be heated. Air, being a bad conductor of heat, does not take up the heat so rapidly as water vapour, for instance, would do. In regard to the slit generator, this is one of the most economical descriptions of generator, but it is not suitable for all kinds of coke. With the coke from some kinds of coal the slag can be run out without difficulty, but with other kinds it is not possible to get rid of the slag or clinker in that manner. The use of gaseous fuel is a question of great interest, not only to gas engineers but in regard to a great many industries. We all know the waste of fuel in many ways is enormous, and it is only by controlling the combustion of fuel that we can prevent this.

Mr. HEAD, as manager for the representatives of the late Sir William Siemens, was glad to respond to the call made upon him by the chairman to join in the discussion. He would first congratulate the meeting upon the circumstance that they were not present to discuss the question of the adoption of regenerative gas furnaces, but to what form they should give the preference. That was a great step in advance, showing that the late Sir William Siemens's work had taken deep root in the minds of gas engineers, and had Sir William Siemens been spared to them, he (the speaker) was sure it would have given him great pleasure to have attended that meeting. The author had commenced his paper by a reference to an application of the Siemens furnace made at Windsor Street station twenty years since. That application was made according to the early form of the regenerative gas furnace, with reversing valves, a form which had received an extensive application at the Paris Gasworks, but it was not considered a success at Birmingham. The reason of that non-success, he recollected, was due to leakage of water into the regenerators, which would have been avoided had the furnaces been constructed with stage floors. The author remarked that there was no finality in the application of scientific principles, a statement which would have been heartily confirmed by the late Sir William Siemens, whose whole life was devoted to improvements in various engineering and scientific appliances, to none of which he gave more attention than to the regenerative gas furnace. He (the speaker) for twenty-three and a half years had had the privilege of assisting him in his civil engineering work, consisting mainly in the development and application of the regenerative gas furnace. This work would now be directed by Mr. F. Siemens, who during the whole time had been associated with his brother, the late Sir William Siemens, in the application of different forms of regenerative gas furnaces to meet the various requirements of manufacturers. The author seemed to think that the Siemens furnace, as applied to the heating of gas retorts, was necessarily coupled with the use of a gas producer outside the setting, and he (the speaker) wished to remove that idea as being an erroneous impression. As the late Sir William Siemens pointed out at the meeting of the Gas Institute at Sheffield last June, the selection of the form of gas producer, whether outside or inside

the setting must depend upon local circumstances, and as a matter of fact he could add that the Siemens furnaces at Halifax and Denton were provided with gas producers inside the setting, this form having also been adopted at Saint Mandé twenty years since with some of the earliest applications made by the Paris Gas Company. The outside gas producer was adopted for certain kinds of fuel, and in Scotland, where the coke was of a hard, slaty nature, it was found easy to work, and the analyses which the author furnished of the gas made in that and other kinds of producers showed quite in its favour, the gas from the former containing about 37 per cent. of combustible elements against 29 per cent. from the latter, thus compensating for the loss of heat by radiation, which was the objection raised against it. The gas producer shown in the diagram in connection with Herr Klönne's type of regenerative gas furnace, as mentioned by the author, was the mere reproduction of one of the Siemens early forms. That form, however, presented certain inconveniences in working which caused the late Sir William Siemens to modify it, shortly before his death, by the substitution of a solid support for the horizontal grate-bars, also by the suppression of the steps in front, in lieu of which an opening was provided at the level of the solid support for stoking. Clinkers would gather on the solid support, and could easily be pushed towards an open space at back, which served for removing them and also for the admission of air to the gas producer. The outside gas producer shown in connection with the Siemens furnaces at Glasgow had been likened to the Dessau or Didier form; but he (the speaker) disclaimed the resemblance, for in the latter case the outlet for gas was placed near the hearth or bottom, so that the outflowing gas would consist mostly of carbonic acid, whereas in the other case the outlet for gas was at the top of the column of fuel, and the analyses already referred to proved the gas to be of superior quality. It would thus readily be seen that this difference between the two apparatus, and there were others, was an all-important distinction. Touching the richness of gas made in producers, the speaker agreed with the author that the greater proportion of carbonic oxide and the smaller proportion of carbonic acid depended upon intensity of heat inside the producer, but this must be coupled with a slow, or at any rate a moderate, rate of combustion. He (the speaker) had personally carried out some experiments for the late Sir William Siemens which he considered settled that point, and dealing with Staffordshire coal in the improved type of Siemens producer he had obtained a gas containing only 2 per cent. carbonic acid with 0.2 per cent. of free oxygen. Ordinary workmen could not, however, be trusted to work under the conditions necessary for obtaining these results, as yet, although he found that in ordinary practice they obtained from Staffordshire coal a gas containing 48.6 per cent. of combustible elements, with only 3 per cent. carbonic acid and 0.8 per cent. oxygen. As mentioned by the author, the arrangement of gas and air jets in the combustion chamber, shown in the diagram of the Glasgow furnace, originated with Mr. Foulis, the well-known gas engineer of the Glasgow Corporation Works, and, with his permission, the late Sir William Siemens adopted it for his gas retort furnaces. To the zig-zag regenerator flues shown in the diagram, with which the late Sir William Siemens had commenced, he afterwards added baffle bricks. By that addition their efficiency had been insured under all conditions of working. He (the speaker) claimed the Siemens furnace to be as efficient as any other regenerative gas furnace, and much cheaper to build, bricks of ordinary size being used throughout, instead of costly and cumbrous special bricks like the one

shown upon the table. The results obtained at gas-works varied a little, but he had furnaces working with only 10lb. of coke to the 100lb. of coal carbonised, which would, he thought, be considered a satisfactory result.

Mr. HEAD asked to be allowed to say a few words touching a remark made by Mr. Paterson as to stoppage of ascension pipes. He (Mr. Head) was satisfied, from experience recently acquired, that stoppages were not due to the intensity of the heat of regenerative gas furnaces but to its misapplication. At Rochdale, a Siemens furnace had been set to work, since about four weeks, without any stoppage whatever of the ascension pipes occurring.

Mr. HACK: I have given considerable attention to this question, and am of opinion that the matter is no longer in an experimental stage. The principle is now well known to most gas engineers. My attention was first called to it on a visit to Paris, where the system was in operation at Clichy. I afterwards became more acquainted with it at our Adderley Street works; and from reading subsequent papers on the subject I determined to give it a fair trial. The theory seemed correct enough, and I started with the object of (1) realising a large saving per cent. in fuel, (2) saving in labour, and (3) increased capacity of the works by a larger yield per mouthpiece. I commenced first with a few of Klönne's settings, and after I added a modification of the Clichy furnace. I have also adopted the system in two or three ways devised by myself. With regard to the saving in labour anticipated, I am sorry to say that so far it has not been realised. The saving in firemen's wages has been more than nullified by the large number of men required to unstop the ascension pipes, which the increased heat caused. This drawback seems to me almost inseparable from carbonising at high heats. With regard to the fuel account, all that I anticipated has been borne out. In some of the furnaces on the Klönne system we have used but 10lb. per 100lb. of coal carbonised with similar settings (nine retorts in a setting). On the ordinary plan we were using 22 per cent. With regard to the Clichy plan, that is found not so economical as against the 22 per cent. formerly required. We are now using in these regenerators 17 per cent. In the remainder of the new settings we have used from 13 to 14 per cent., all of them showing a considerable saving in fuel, and I think that every gas engineer should no longer hesitate in adopting the new principle. In doing so at Saltley, I have had to contend with some rather difficult circumstances, having to alter benches that were originally constructed for ordinary furnaces; but even with these disadvantages I am so thoroughly satisfied that the principle is the correct one, that I hope to see it applied shortly to nearly every bench in my works.

Mr. SMITH CASSON: With the chairman's permission, I should like to say a few words on gas furnaces, having had several years' experience with them, the result being that I have come to the conclusion that for most manufacturing purposes regenerators, which, as is well known, are most costly in construction and maintenance, are altogether unnecessary, provided the air is heated in a proper manner, which is the case at the Earl of Dudley's Round Oak Iron-works, where the bulk of the iron is puddled, ball-furnaced, and reheated on my system. As showing the heat that we get, I may state that we frequently have occasion to heat 25cwt. "piles" or "blooms," which we easily do in an hour's time, reheating the same in 20 minutes. We have also melted wrought-iron scrap in crucibles in about 30 minutes, which proves the intensity of heat that we obtain. The gas is made in the ordinary producer, and the air heated in a somewhat similar manner to the Klönne system,

but if anything simpler, the furnace-man having perfect and instantaneous control over the gas and air, both being under pressure. I quite agree with Mr. Head in his remarks about the Tusard producer, as gas is drawn off too low down, the Siemens arrangement, as shown on the Glasgow retort drawing, being better in my opinion. I have recently taken out a patent for restoring the hydrocarbons to gas-coke, by dipping it in crude petroleum, which, I believe, will enable gas engineers to heat their retorts with the gas coke they have in many instances such a difficulty in disposing of. To prove what the petro-coke is capable of doing I tried some in a puddling furnace, and in an hour and three quarters produced 4cwt. of puddled bars, with 5cwt. of gas coke, mixed with 13 quarts of petroleum. As may be imagined there was an entire absence of smoke from the chimney.

Mr. WEST: As gas engineers, you may be sure that we are very much interested in the question of regenerator furnaces. I have never had the opportunity before to state in public my view on this important question. Some of you are aware that Mr. Stevenson, our president, has taken a great interest in this matter, and I think we are all very much indebted to him, although he has not had a very good opportunity of getting experiments worked out himself. I may tell you that he was the first to assist me, between five and six years ago, in putting up some furnaces on the Liegel system at Maidstone. These furnaces were arranged with slits, and with the kind of coals we were then using, we managed to get very excellent heats, but we found that if we changed the coal we got into difficulties on account of not being able to run off the slag systematically, and I came to the conclusion that these furnaces would be objectionable in the Midland districts, where a variety of coal was used. At Manchester we decided to erect regenerator furnaces at our new works, and there we have to deal with various canals and coals containing from 5 to 30 per cent. of ash, and it became a question which was the best furnace to adopt. I may say that we decided to put up a number of Siemens's, some of Klönne, and some devised by myself. We have not been able yet to test the relative merits of these systems, but I may say I was led to adopt the Klönne furnaces from what I saw our friends were doing in Birmingham and other places, and I think it right to say I have been especially pleased to find that the two engineers in this town have practically solved the question. As I told you, I began very early to introduce these furnaces into England, with the assistance of our president, but was unable to bring them out so perfectly, for want of practice, as your engineers have done here. It is very gratifying to hear Mr. Hack say that he has brought down the percentage of fuel to 10lb. per every 100lb. of coal carbonised, which is proof that he has been most energetically at work and progressing in the right direction. With reference to the remarks made by Mr. Head about stopped pipes, they arise simply on account of the intense heat generated. This, however, is another subject altogether apart from regenerator furnaces, and should not be attached to it. There are one or two advantages connected with regenerator furnaces that I think have not been sufficiently dwelt upon. In some districts a saving of fuel may be of value, but in Manchester this is not worth any consideration, for at the present time we are selling coke at 3s. 4d. per ton. I attach great importance, however, to the extra volume of gas that can be produced per retort, the ease with which the firing is accomplished, and the greater durability of the retorts.

REPLY.

Mr. HUNT, in replying, said he quite agreed with

Mr. West that gas-makers were greatly indebted to Mr. Stevenson for his efforts in forcing upon their attention this important subject of gas firing, and it must be very gratifying to them to know how rapidly the system is now spreading, and with what good results. He likewise endorsed what Mr. West had said in reference to the cause of stopped pipes. That this was very much a matter of high heats he had no doubt whatever, any more than he had as to what were the principal remedies to be applied, namely, moderate heats and speedy removal of the tar from the hydraulic main. No system of heating could claim immunity from stopped pipes. He had been very interested in hearing of the new use for gas coke developed by Mr. Casson, but presumed that his process was not applicable to the manufacture of illuminating gas. As to the difference in price between Manchester and Birmingham gas coke, he was of opinion that the Birmingham consumer had the best bargain, although paying 10s. per ton as against 3s. 4d., because the Manchester coke was largely made from cannel, and was consequently of a quality that he was afraid would in this district scarcely command a sale at any price. With reference to the exception taken by Mr. Head to his compound of the Didier with the Siemens generator, all he had to say was that there was an exact similarity between the two, in so far as both were hearth generators. Beyond that he had not expressed any opinion. He was glad to hear that Mr. Head was turning his attention to placing the producer within the setting. Hitherto the Siemens system had been identified with the detached generator, as shown upon the drawing. Mr. Head's memory was accurate when he said that one of the difficulties experienced in the working of the original Siemens system at Windsor Street was the accumulation of water in the flues; but this had nothing to do with the ultimate decision in regard to the system, it having been overcome during the latter part of the trial. The explanation sought for by Mr. Paterson, as to the different proportions of combustible gases existing in the Saltley and Glasgow furnaces, was to be found in the fact that with the latter steam was largely employed. He was of opinion that the proportion of CO<sub>2</sub> existing in the furnace gases was very moderate, for if he recollected rightly about 8 per cent. was the quantity shown to be present in the gases from the Schilling generator. He could not accept Mr. Stevenson's suggestion as accounting for the presence of so large a percentage of free oxygen in the chimney gases from the Saltley furnaces. Any leakage in the flues was not difficult to detect, and he adhered to the opinion that the excess was due to imperfect regulation of the air supply. He contended that it was absolutely impossible to settle the question of economy in regard to gas firing without recuperation in any other way than by applying the gas as he had done in the manner described in his paper.

## MEETINGS FOR 1881.

MARCH 17TH.—(1) On the Effect of Temperature in Dyeing. By Professor Mills and Mr. Rennie. (2) On the Production of Ammonia from the Nitrogen of Minerals. By Mr. Beilby. (3) On the Distribution of the Gases in the Leaden Chamber. By Mr. Maectear.

APRIL 8TH.—(1) On Algin. By Mr. Stanford. (2) On some Points in the Technology of Oil of Vitriol. By Mr. Maectear. (3) On Nickel Vessels for Chemical Operations. By Professor Dittmar.

APRIL 29TH. (Special meeting).—Discussion on International Methods of Testing and Sampling. Introduced by Mr. Tatlock.

MAY 13TH.—(1) On Different Methods of Producing Cold Artificially. By Mr. Coleman. (2) On the Composition of Tobacco. By Dr. Clark.

## Journal and Patent Literature.

## I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*A New or Improved Composition for Preventing and Removing Incrustation in Steam and other Boilers.* S. Lattuada, Milan, Italy. Eng. Pat. 2747, June 2, 1883. Not proceeded with.

"I MIX together about 7 parts by weight of sal-ammoniac, 4 parts of gambier or catechu, 1 part of powdered gall nut, and 1 to 2 parts soda. This mixture applied in about 1,000 times its weight of water prevents formation of calcareous or saline incrustation, and has the effect of detaching such incrustation, and also of preserving the metal against corrosion."

*Improvements in the Manufacture of Acid-proof, Porous Masses of Clay, permeated with finely-divided Carbon, suitable for Filtering and Refining Operations.* Wilhelm Olschewsky, Berlin. Ger. Pat. 23254, Nov. 24, 1882. Addition to Pat. 19589, Jan. 31, 1882.

For the preparation of acid-resisting masses for purposes of filtration, very porous clay, granulated in accordance with the directions contained in the original patent, is warmed with concentrated hydrochloric acid, until the extraction of all soluble constituents is completed. The sufficiently hard and very porous unattached portion is washed and dried, and then impregnated with tar, liquid glue, or petroleum residues, which, on heating, in the absence of air, cause the clay mass to become permeated with finely-divided carbon.—W. D. B.

## II.—FUEL, GAS, AND LIGHT.

*On Kumberg's New Petroleum Lamp and B. Hoff's "Multiplier."* Dingl. Polyt. Journ. 250, 409.

THE committee of the Russian Chemical and Physical Society have awarded to Kumberg the premium for a

lamps suited for use with the oils of specific gravity 0.865 to 0.875, obtained by distilling Caucasian petroleum. It is hoped that this invention may enable Caucasian petroleum to compete successfully in European markets

with that obtained from America. Hoff's multiplier is an apparatus for distilling lamp oils. Petroleum, when heated above its boiling point, is decomposed into volatile hydrocarbons containing but little carbon, and others less volatile and richer in that element. By increasing the temperature the latter undergo a similar change, and in course of time the whole of the original liquid may be converted into lighter oils and residual carbon. The construction of the multiplier will be understood on reference to the annexed figure. From the still *a* the outlet pipe *c*, which is equal in length to one-third of the height of the still, and enlarged at *d* to a globe with a diameter of one-third of the length of the pipe *c*, communicates with the cooling pipe *e*, 7 metres in length, and terminating in the water-cooled condenser *f*. From *f* the tube *g* carries away the condensed products to the collecting chamber *h*, from which the flue *k*, passing through the roof of the building, draws off inflammable gases. The proportions of the still head are so arranged that vapours of oils with a specific gravity higher than 0.83 are there condensed, while the lighter products pass over into the condensing tube. The decomposition of the petroleum sets in at a temperature of 300°. It is essential that the fire be so maintained that the fuel in the still is thoroughly boiling. The advantages claimed for this still are that good lamp oil of specific gravity 0.81 to 0.83 may be readily obtained to the extent of 95 per cent. of the petroleum taken; and since the oil from the waste of the sulphuric acid refinery may be entirely recovered by it, an important reduction in the cost of producing lamp oil is effected.—W. G. M.

*Improvements in Coke Ovens.* Dingl. Polyt. Journ. 250, 456.

THE apparatus represented in Figs. 1, 2, and 3 has been patented (Ger. Pat. 21455, 1882) by A. Hiltawski. The slack to be coked is fed into the chambers *A* through the openings *a*. The evolved gases pass the openings *C* into the side chambers *D*, thence through *e* into *f*, lastly through *g* into the main flue *h*, whence they pass to the chimney. The draught is regulated at *e* by dampers to which access is given through the openings *O*. The openings *S* in the floor of the coking chambers *A* also serve as outlets for the gases. These are cleared from time to time during the process by means of rakes worked through *v*. The openings *e* are similarly cleared through *z*, the cinders being raked out through *o*. The supply of air for the complete combustion of the smoke is regulated by dampers *k* in the front and hind walls of each gas chamber.

C. Sachse (Ger. Pat. 22111, 1882), Figs. 4 and 5, constructs the roof of horizontal ovens with an interrupted slit. Into this, heavy slabs are introduced, which, by pressing on the charge of coal, cause the production of a dense coke. In a later patent (22826, 1882) a second slit is provided, through which the charge may be introduced without having to remove the slabs. This second slit is closed air-tight during the coking. The arrangement of the flues *m*, *n*, *o*, is explained by the drawing. The gases pass down the vertical flues *k* into *m*, thence through *u* and *o* into *v*.

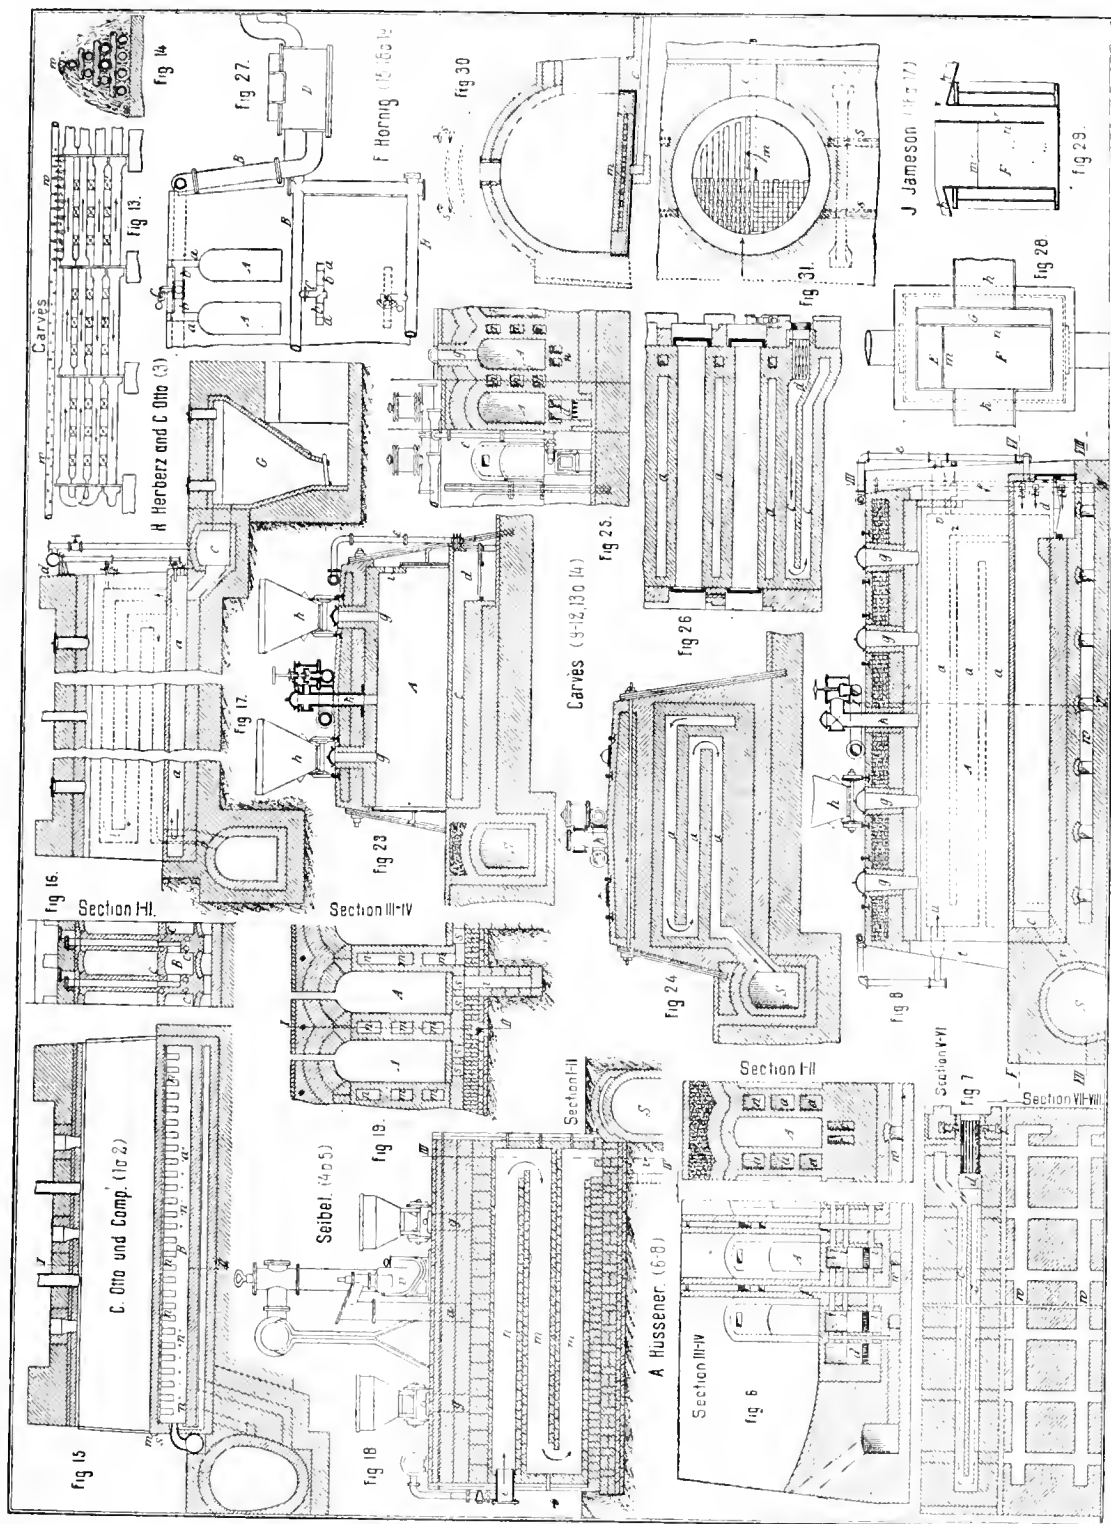

In the shaft coke oven, Fig. 6, of E. Franzen (Ger. Pat. 21867, 1882) the gases evolved in the coking chamber *H* pass through the openings *e* into the vertical canal *c*, where they are mixed with atmospheric air, drawn in by way of *a* and *s*, *a* being in direct contact with the outer air. The products of combustion pass by way of *G* into the chimney.

F. Lürmann (Ger. Pat. Suppl. 17203, 1881), Figs. 7, 8, 9, and 10, has adopted in continuous coking ovens a slit, as at *S*, Fig. 10, in the floor of the coking chamber *A*, in close proximity to the door *F*. This slit is cleared from time to time by raking. Through *S* air can be admitted directly into the centre of the coking mass. Instead of passing the evolved gases through a single opening *z*, and then determining with the air in *C* an intense combustion at a point where the heat is least required by the coking mass, other openings are provided as at *a*, by which means the heat is caused to do work on the coal and prevented from acting injuriously on the material of the oven. Where the method of separating the condensable products of

prevent it attacking the coke. The combustion of the gases takes place in D by means of air admitted through *m* and *o*, the product of combustion passing by way of

be provided in the roof of the chamber. Lürmann's extracting tongs (Figs. 11, 12, 13, and 14), for removing the charge from coke ovens, is a locomotive apparatus,

*i* into *j*. The down draughts are indicated by *d d*, the up draughts by *f f*, the horizontal by *e e*. In addition to the gas exits *a* in the side walls similar exits *g* may

It consists of a handle *p*, with a ring at *r*: *p* terminates at its other extremity in the screw *v*, working in union with the screw *s*. The levers *t* are connected with *z*, the

extracting tongs proper. The handle *w* being turned to the left, the screw *s* is advanced along the thread *r*, and the tongs are opened by means of *t*. The apparatus is then brought to the door of the oven to be emptied, the tongs are pushed home, and by the reverse turn of the handle *w* caused to grip the mass of coke, which is then drawn by any suitable mechanical means applied at *r*.

C. Otto and Company (Ger. Pat. 20908, 1882), Figs. 15 and 16, have devised an arrangement with the object of introducing air at any required point, which consists of small passages *C* (Fig. 16) in the floor, roof, and sides of the main flue (Sohlkanal), the entrance of the air being controlled by stops *s* at the extremities *m*.

H. Herber and C. Otto have patented (Ger. Pat. 17873, 1881) an arrangement which dispenses with the auxiliary stoves hitherto used in the case of ovens adapted to the recovery of the volatile by-products. According to their plan, a sufficient number of generators *G* (Fig. 17) are worked in connection with a group of ovens, and the hot gases from the generators are conducted through *C* into *a* of the ovens; here they meet with the gases returned through *d* from the condensation apparatus and with air admitted through *e*.

L. Chemut describes a coke oven (*Ann. Ind.* 1883, p. 369), Figs. 18 and 19, worked by Seibel, in Campagnac, which is said to yield 73 per cent. coke from a coal yielding only 64 per cent. by the crucible test. The ovens *A* (Fig. 19) are 6m. long, 0·7m. wide, and 1m. high. They are charged through *g* with 5 tons of coal. The evolved gases pass through *a* to a common chamber *v*, where the condensable products are removed, the gases being returned by way of *c* to *u*. This arrangement does not appear to be essentially different from that of T. Semet and Solvay (*Dingl. Journ.* 248, 212). The yield moreover is probably over-estimated.

An exhaustive discussion of recent improvements in coke ovens will be found in *Stahl und Eisen*, 1883, p. 397, from the pen of A. Hüssener. Details are given of the working of nine small Lürmann ovens—previously described—during a period of 17 months ending March, 1883. A mixture of equal parts of cannel (Westphalian) and anthracite was employed, 4573·5 tons of this mixture yielding 3660·5 of coke, *i.e.*, 80 per cent. The dimensions of these ovens are 9m. by 0·5m. by 1m. high. Objections appear to be taken by certain operators to the quality of the coke and the labour of drawing the charge in the case of these ovens; but as these have to do with the quality of coal employed and the mechanical details of working, these defects, it is suggested, may be readily overcome, and the oven is recognised as, on the whole, a decided improvement on previous forms. The following details are given of the working of the Sachse oven, previously described, during a period of 32 days. To show the effect of weighting the charge, a parallel experiment was made in which the weighting was omitted. Results—

	Aggregate Coke.	Large Coke.	Small Coke.
With weighting . . . .	65·8 composed of 80·62	19·37	
Without weighting . . .	61·5 composed of 69·06	30·94	

The advantage of weighting the charge is thus established. A series of experiments with the Carvès oven, conducted by Hüssener and K. Möller, has led to the foundation of a Coal Distillation Company, working with 50 of these ovens, built expressly, and on a somewhat improved plan, at Gelsenkirchen in Westphalia. The original form of these ovens is sufficiently explained by Figs. 23 to 26. The improved form is set forth in Figs. 20 to 22. The retorts are 9m. long, and of conical form. In the middle they are 0·575m. broad by 1·8m. high. They hold a charge of  $\frac{5}{8}$  tons of slack. It was found advantageous to use a cannel coal. The following are the details of the work which has been done by these ovens, in continuous operation, since November, 1882. Output:

	Per cent.
Large coke . . . . .	75·0
Small coke . . . . .	0·8
Dust . . . . .	1·2
Tar . . . . .	2·77
Ammonium sulphate . . .	1·10

The tar obtained was limpid, and yielded on distillation 8·8 per cent. of volatile liquids, 39·5 per cent. of pitch,

with 1·7 per cent. loss. See this Journal, vol. II. [12], page 500. The further treatment of the distillate gave the following:—

	Per cent.
Benzol (b.p., 80° to 100°) . . . . .	0·59
Benzol (b.p., 100 to 110°) . . . . .	0·19
Naphthalene . . . . .	0·39
Phenol . . . . .	1·39
Anthracene . . . . .	0·95

These ovens have been adopted in this country, and a description of 25 of these erected at Crook (Durham) is given by R. Dixon in *Iron*, 1883, 22, 260. See also this Journal II. [10], page 404. The cost of erection is given at £5,500. In 215 days' working 7,042 tons Durham coal yielded 5,424 tons 11 cwt., or 77 per cent. coke, 2·8 per cent. tar, and 12·6 per cent. gas liquor.

C. Demant (*Rev. Univ. d. Mines*, 1883, 13, 593) gives the following details of the working of the Semet ovens: 145 tons of dry coal yielded 115·3 tons of large coke, 0·98 of small, and 1·58 of dust, together, 114·5 tons, *i.e.*, 79 per cent. The quantity of tar from the same was 2,719 kilos.

F. Hernig has patented (Ger. Pat. 21908, 1882) the apparatus for collecting the tar and ammonia from the distillation of coke represented in Fig. 27. The exits *a* from two ovens, placed side by side, are connected by a cross-canal *b*, containing a two-way valve *c*, by means of which either oven can be brought into connection with *B*, and through this with *D* and a series of condensers. The condensed liquids flow through *E* (Figs. 28 and 29) back again into *D*, thence by way of *m* into *F*, where, in consequence of the heat, a more complete separation of the tar is effected. The tar flows under the partition wall *n* into *G*, and thence by way of *h* to the store tank. The ammonia water flows through *k* into a second tank.

Lastly, notices are given of papers by J. J. Jameson on this subject in *Engineering*, 1883, 36, 255, and in this Journal, 1883, p. 114; also II. [10], p. 405. In plan and section the Jameson ovens are shown in Figs. 30 and 31.—C. F. C.

#### IV.—COLOURING MATTERS AND DYES.

##### *Improvements in the Manufacture of Laundry Blue.*

M. H. Hargreaves and T. L. Hargreaves, Hull, and J. E. Hargreaves, Freshwater. Eng. Pat. 2524, May 21, 1883.

LAUNDRY blue is to be manufactured by "grinding together ultramarine, gum arabic or acacia, and sanitas." For the latter ingredient, "terebene, carbolic acid, borax, salicylic acid, or other disinfectant of like nature" may be substituted.

##### *Improvements in the Manufacture of Tannic Black, and its Application for Paints and other Useful Purposes.*

W. G. Gard and T. H. Copley, Dunstable. Eng. Pat. 2549, May 22, 1883.

"LEATHER waste, or any other material containing tannic acid," is "heated to from 180° to 200° F.," with solution either of soda or of acetate of soda, and the liquid so obtained is then treated by a salt of iron. The "tannic black" which precipitates is then separated from its mother-liquor, washed, and dried. It may then "be ground into paint in the ordinary way," or may be employed "mixed with albumen or casein" in calico printing.

##### *Method for the Preparation of Paranitrobenzylidene Chloride.* Farbwerke vormals Meister, Lucius, and Brüning, Höchst-on-the-Maine. Ger. Pat. 24152, Jan. 5, 1883.

PARANITROTOLUENE is treated with chlorine at a temperature of 130° to 160° until the calculated quantity of the gas has been taken up. The product of the reaction is first washed with water, then with caustic soda, and finally again with water, and then recrystallised from alcohol. The paranitrobenzylidene chloride thus obtained forms paranitrobenzaldehyde on treatment with concentrated sulphuric acid.—F. M.

*Method for the Preparation of Nitro-leuco Bases of Triphenylmethane, its Homologues and similar Hydrocarbons.* Farbwerke vormals Meister, Lucius, und Brünning, Höchst-on-the-Maine. Ger. Pat. 23784, Jan. 5, 1883.

THE nitro-leuco bases are obtained from aniline, toluidine, xylidine, naphthylamine, methylxylidine, and diphenylamine by treating these bases with paranitrobenzylidene chloride, paranitrobenzylidene bromide, paranitrobenzylidene diacetate or paranitrobenzylidene glycolic ether, in the presence of a solvent such as petroleum spirit, benzene, alcohol, etc., at the boiling heat of water. Similar leuco bases are obtained from paranitrobenzylidene anilide, toluidide, or xylidide by heating these compounds with the salts of the bases mentioned above in presence of a solvent.—F. M.

*Modifications in the Method for the Preparation of Artificial Indigo.* Badische Anilin und Sodafabrik, Ludwigshafen-am-Rhein. Ger. Pat. 23785, Jan. 13, 1881. Addition to Pat. 21592, Aug. 12, 1882.

THE orthonitroacetophenone described by Gevekoht (*Bericht d. deutschen chemischen Gesellschaft*, 15, 2084) is in the same manner as acetophenone converted into brominated or chlorinated substitution products which contain the halogene in the methyl group. By suitable reducing agents these substitution products can be converted into indigo blue.—F. M.

*Method for the Manufacture of Red Colouring Matters by the Action of Paradiamines upon the Amido Ethers of the Phenols.* Kalle and Company, Biebrich-on-the-Rhine. Ger. Pat. 24229, Oct. 27, 1882.

IN the same manner as safranine is formed by the oxidation of a mixture of para-diamines and primary monamines of the benzene series (aniline, toluidine, etc.), similar colouring matters can be obtained by combining para-diamines with the amido-ethers of the phenols under the influence of an oxidising agent. One molecule of the para-diamine and two molecules of the amido-phenol ether in aqueous solution are treated with potassium bichromate or another oxidising agent. The colouring matter formed is precipitated with salt. In the case of paraphenylenediamine and anisidine being used the reaction seems to take place in accordance with, the following equation:—

In place of the para-diamines, their substitution products (dimethylparaphenylene diamine, etc.), or such compounds which by reducing agents are converted into para-diamines—for instance, nitrosodimethylaniline and imidodichloroquinone—may be used. In this latter case the employment of oxidising agents is unnecessary, as these bodies act themselves as such. Of the amido-phenol ethers the ortho compounds (orthoanisidine, orthoamidophenetol, orthoamidobutylphenol, etc.) are the most important; they can, however, by one half, be substituted by the corresponding para compounds. One half of the amidophenol ether may likewise be replaced by other monamines, such as aniline, toluidine, or dimethylaniline. Colouring matters of this class are prepared by the oxidation of a mixture of equal molecules of the amidophenol ether and paradiamidodiphenylamine,  $(\text{NH}_2\text{C}_6\text{H}_4)_2\text{NH}$ .—F. M.

*Method for the Manufacture of a Blue Colouring Matter.* J. F. Espenscheid, Friedrichsfeld, Baden. Ger. Pat. 23422, Feb. 5, 1882.

WHEN nitrosodimethylaniline is treated in an acid solution with sulphur chloride sulphur is separated & the liquor assumes a brownish or yellowish red colour. The solution contains now a sulphur compound, from which, by treatment with reducing agents (zinc dust, iron filings, etc.), part of the sulphur is abstracted. By oxidising the colourless solution thus obtained with ferric chloride, a blue colouring matter is formed which can be separated by adding common salt or zinc chloride to the liquor.

F. M.

*Method for the Synthetic Preparation (through abstraction of water) of Organic Compounds by the Employment of Acid Alkaline Sulphates.* Actien-Gesellschaft für Anilinfabrikation, Berlin. Ger. Pat. 23775, July 27, 1882.

INSTEAD of sulphuric acid or zinc chloride, which are now being used as water-abstracting agents, alkaline bisulphates are employed, whereby some reactions proceed much more smoothly than with sulphuric acid or zinc chloride. A number of condensations may be effected with alkaline bisulphate, in cases where sulphuric acid does not give a satisfactory result or cannot be employed at all. Potassium, sodium, or ammonium bisulphates are used in the following processes: (1) For the condensation of aldehydes with secondary and tertiary monamines, namely, benzaldehyde, nitrobenzaldehyde, oxybenzaldehyde, and benzaldehyde sulphonic acid on one hand, with methyl-, ethyl-, dimethyl-, diethyl-, diamyl-, aniline, diphenylamine, and methyldiphenylamine on the other. (2) For the condensation of aldehydes with phenols under employment of acetic aldehyde, chloral, acrolein, valeral, benzaldehyde, its nitro- and oxy- derivatives and sulphonic acid on one hand, and phenol,  $\alpha$  and  $\beta$ -naphthol, cresol, resorcin, orcin, pyrocatechin, pyrogallol, and the methyl-, ethyl-, etc., ethers of the polymeric phenols. (3) For the condensation of alcohols with phenols, such as methyl-, ethyl-, isobutyl-, amyl-, and benzyl alcohol, with phenol, nitrophenol, cresol, resorcin, orcin, pyrocatechin, pyrogallol, salicylic acid, and gallic acid.—F. M.

*Method for the Manufacture of a Black Pigment Colour from Coal-tar Pitch.* Emil Heusser, Dürkheim, Pfalz. Ger. Pat. 24231, Jan. 23, 1883.

THE pitch is extracted with warm light tar-oil or benzoline. A solution is formed which on evaporation leaves a mass resembling native asphaltum. The residue left after extraction forms a black colour of great covering power.—F. M.

*Method for the Manufacture of Glass and Soluble Silicates in Pit Furnaces.* Emil Heusser, Dürkheim, Pfalz. Ger. Pat. 23950, Jan. 23, 1883.

THE glass mixture, consisting of sodium sulphate, calcium sulphate, and silica, is made up with coal pitch into briquettes, which are dried in the air. These briquettes are melted in a pit furnace under employment of a hot-air blast, whereby the sulphur is given off in the shape of sulphurous acid. The sulphurous gas is utilised for the production of sulphites of lime or soda. Soluble silicate is obtained in the same manner, the addition of calcium sulphate being omitted.—F. M.

*Improvements in the Manufacture of Colouring Matters.* Paul Joachim Meyer, Berlin. Eng. Pat. 1788, April 9, 1883.

THIS invention has for its object the production of derivatives of isatin, and their conversion into indigo derivatives by the known methods of transformation. The inventor acts upon amines, such as aniline and its homologues and their alkylised or haloid derivatives, or the corresponding diamines, with a dihaloid acetic acid, i.e., by dichlor-, dibrom-, or diiod-acetic acid, in the proportion of one molecule of the acid to four molecules of the base. The reaction is effected by fusing the constituents together at a temperature of a water-bath, or by digesting the solutions in open or closed vessels. The completion of the reaction is indicated by the copious liberation of hydrochloric acid, and the product, after being washed with water, to free it from the hydrochloride of unaltered base, is crystallised from alcohol. The reaction is said to give rise to the formation (taking paratoluidine as an example of a base) of "paratoluyliised paramethylisatin—that is to say, of paramethylisatin in which the place of one atom of oxygen thereof is taken by the rest [residue?] of paratoluidine," and the inventor gives the following equation—

The "paratoluyliised paramethylisatin," on treatment with strong acid or alkali, decomposes into paratoluidine and paramethylisatin in accordance with the equation—

The inventor also gives equations showing that the ethers, amides, and aldehydes of the dihaloid acid may be used instead of the acid itself. Paramethylisatin is very similar to ordinary isatin, and can be converted into paramethylindigo, which can be used to replace ordinary indigo.—R. M.

*Modifications in the Method for the Preparation of Red Colouring Matters from Pyridine and Quinoline Bases.* Patented under 19306. Emil Jacobsen, Berlin, Ger. Pat. 23697, Dec. 16, 1882. Addition to Pat. 19306, Feb. 14, 1882.

WHEN the process described in the first patent is modified by substituting benzyldichloride, bromide, or chlorobromide for benzotrichloride—that is, when one molecule of either of these bodies is heated with two molecules of a pyridine or quinoline base and a small quantity of zinc chloride—red colouring matters are formed, closely resembling but not identical with those obtained by the former process. The colours are obtained as sparingly soluble zinc double salts, which by heating with chlorosulphonic acid or fuming sulphuric acid are transformed into sulphonic acids, the alkaline salts of which are readily soluble. These colouring matters are not produced from pure quinoline, but only from that obtained from coal tar, which besides quinoline contains quinaldine, the presence of both bodies being necessary in the formation of the colours. The best results are obtained when equal molecules of quinoline and quinaldine are heated with benzotrichloride, in which case the bluish-red colouring matter with yellow fluorescence (see Ger. Pat. 19306) is produced. The homologues of quinoline and quinaldine behave in a similar manner.—F. M.

*An Improved Method of Producing a Yellow Dye.* Gustav Adolph Bang, Leeds. A communication from Dahl and Co., Barmen, Germany. Eng. Pat. 1964, April 18, 1883.

ONE part of alphanaphtholmethyl ether is heated to 90° C. with four parts of fuming sulphuric acid containing from 10 to 15 per cent. of anhydride till a sample, on being diluted with water and warmed with nitric acid, no longer gives a precipitate. The mixture is then diluted with ten parts of cold water and warmed with two parts of nitric acid. After nitration the mixture solidifies on cooling to a crystalline mass, which is collected, pressed, and converted into the potassium salt.—R. M.

*New or Improved Process for the Manufacture of Ulmin-brown.* Herbert John Haddan, Kensington. A communication from la Banque Industrielle de Belgique, Paris. Eng. Pat. 2009, April 20, 1883.

ACCORDING to this invention the manufacture of ulmin-brown is carried out by macerating the wood for several days with caustic alkalis or alkaline carbonates, at an elevated temperature, the mass being occasionally boiled. The woods specified are mahogany, birch, cedar, chestnut, oak, elm, quebracho, sumach, etc. The alkaline liquid is saturated with acetic acid, a decoction of tannic acid added, and the mixture evaporated. The inventor states that the various tannins to be added to the extracts are to be selected according to their reaction with iron salts, and he gives the details of the preparation of ulmin-brown for "charging silk."—R. M.

*Improvements in the Manufacture of Colouring Matters Suitable for Dyeing and Printing.* John Erskine, Glasgow. A communication from Carl Rumpff, Elberfeld. Eng. Pat. 2411, May 12, 1883.

IN a previous patent (1225, 1881) the author described a new monosulphonic acid of betanaphthol obtained by

acting upon the naphthol with sulphuric acid at a comparatively low temperature. The new acid is betanaphthol-alpha-sulphonic acid mixed with a certain quantity of the betanaphtholbetasulphonic acid of Schäffer. In the former specification a method of separating the two acids was described, which depended upon the solubility of the sodium salt of the new acid and the insolubility of the sodium salt of Schäffer's acid in alcohol. In the present patent the author describes a method of separating the isomeric acids by acting upon the mixture in the usual way with diazobenzene and its homologues, diazonaphthalene, etc. Under these circumstances, Schäffer's acid is the first to combine with the diazo-salt, and the colouring thus produced is salted out and removed by filtration, the filtrate containing the required alpha-sulphonic acid. The amount of betasulphonic acid in the mixture is first ascertained in a sample "by well-known chemical means," so that the amount of diazo compound required to remove this beta acid can be added exactly.—R. M.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

*The Production by chemical means of Permanent Embossed Designs upon Plush and other Woolen Fabrics.* W. Spindler, Berlin. Ger. Pat. 23710, Feb. 7, 1883.

COMPOUNDS such as soda, hydrochloric acid, nitric acid, tin-salt, potassium bichromate, and calcium sulphide, which have a corrosive action upon wool, are made up with starch into paste of convenient thickness, and the fabrics are printed with such paste either by hand or machinery. The printed fabrics are then dried, steamed, and washed, whereby the embossing becomes apparent. W. D. B.

*Improvements in the Process of Rendering Wood Celluloses, Textiles, and other Products Uninflamable and Incombustible.* F. K. de Stasieki, London. Communicated by B. Hoff, Jaroslau, Austria. Eng. Pat. 1744, 1883.

THIS invention consists in forcing "into the pores of the wood or other organic material to be treated," under a pressure of from 4 to 8 atmospheres, either a solution of 20 parts of sulphate of magnesia and 5 parts of sulphite of ammonia in 100 of water, or a solution of 15 parts of sulphate of magnesia, 5 parts of sulphite of magnesia, and 5 parts of either sulphate or chloride of ammonium in 100 of water. After having been impregnated with one or the other of these solutions, the wood or other material is to be coated with a varnish made by heating "4 parts of native red oxide of lead with 5 parts of a fatty oil," dissolving "20 parts of the soap thus obtained in 100 parts of green heavy petroleum of 0.96 sp. gr. (this is a residuum of petroleum distilling factories)," and adding to the product "20 parts of linseed oil varnish." It is said that wood so treated will "resist a heat of even 400° to 600° C., and under such conditions produces very little smoke or gas prejudicial to free breathing. Being a very bad conductor of heat, only that part of the wood which is in contact with the flame is warmed."

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Oxidation of Oil in Turkey-red Dyeing.* F. Schatz. Dingl. Polyt. Jour. 250, 9.

IN the article "On the Oiling and other Processes in Dyeing Turkey Red" (1882, 247, 38), there were incidentally mentioned steaming and hanging, but the author expressed himself in such a manner as to give rise to the construction that the less stable compounds of the fatty acids were thereby destroyed. The reason which induced him to come to this conclusion was the peculiar smell, reminding him of boiling soap-ley and slightly-burnt fats escaping from the steam-cot under certain conditions. Afterwards this conclusion was found to be incorrect. It is well known that for turkey-red dyeing the castor oil is treated

with sulphuric acid. If care be taken to wash out the glycerin completely, the above-mentioned smell is hardly at all noticed on steaming. If the glycerine be intentionally left in, or else if, as must happen sometimes in manufacturing practice, the glycerine be insufficiently removed, then the smell in question reappears, a proof that it is due to glycerine-sulphonic acid. Steaming produces an oxy-acid by separation of sulphurous acid, and a similar oxidation takes place on hanging in the air.

*Improvements in Dyeing Loose Cotton Black.* Gustav Jagenburg, Rydholm. Ger. Pat. 23357. Jan. 16, 1883. Addition to 20691, July 1, 1882.

IN place of the steaming recommended in the original patent, it is sufficient in many cases to dry, at a temperature of from 40° to 60° C., the loose cotton which has been saturated with logwood solution, finally developing the colouring matter in a cold bath under diminished pressure.—W. D. B.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Improvements in the Manufacture of Lime.* W. Kemp, Millers Dale. Eng. Pat. 1692, 1883. Not proceeded with.

THIS invention relates to the calcination of limestone "in what is known as the continuous drawing kiln," and consists "in charging the above-named kiln with alternate layers of fuel" and limestone "of a thickness much greater than has hitherto been the practice." The advantages claimed by the inventor are economy of fuel and "a more speedy calcination" of the limestone.

*Improvements in the Obtaining of Ammonia from Coal Gas.* W. J. Cooper, Westminster. Eng. Pat. 2669, May 29, 1883.

"IN the manufacture of coal gas there is a considerable waste of ammonia at the discharge from the condensers, owing to the strength of the ammoniacal liquor leaving the condensers." To avoid this loss of ammonia, the author of this invention proposes to feed enough water into the condensers "to dilute the ammoniacal liquor so that it is discharged from the condensers in such a diluted state that practically it will not yield ammonia to the atmosphere." The quantity of water proposed to be used is ten gallons per ton of coal carbonised.

*Improvements in the Separation and Utilisation of the Alkali used in the Extraction of Crude Carbolie Acid from Coal Tar or Coal-tar Oils.* J. Lane, Elland, and D. V. Steuart, Manchester. Eng. Pat. 2469, May 17, 1883. Void, by reason of not filing final specification.

THIS invention consists in substituting for the method of "washing coal-tar oils with a dilute solution of caustic soda, thus forming carbolate of lime, from which the carbolie acid is afterwards disengaged by sulphuric acid, soda sulphate remaining as a by-product," the decomposition of the "carbolate of soda" by sulphuretted hydrogen. The inventor proposes to treat the resulting sodium sulphide "by lime, when a sulphide of lime is formed and precipitated, and the alkali becoming disengaged and reconstituted, its solution, after settling, is fit to be again used."

*An Improved Method or Process for the Purification of Alkaline Solutions.* T. Glover, Runcorn. Eng. Pat. 2,734, June 1, 1883.

THIS invention consists in the use of native carbonate of zinc for the decomposition of the sodium sulphide contained in Leblanc soda-makers' vat liquors. The two bodies react upon each other to produce sodium carbonate and zinc sulphide.

*Improvements in the Manufacture of Hydrate of Strontia and Hydrosulphide of Sodium.* C. F. Claus, London, Eng. Pat. 2648, May 28, 1883.

STRONTIUM sulphide is to be formed by furnacing stron-

tium sulphate in admixture with carbonaceous matter. The strontium sulphide is to be boiled with water, so that a solution of it from 25° to 30° T. may be obtained. On cooling, this gives crystals of strontium hydrate, and a mother-liquor consisting of solution of strontium sulphhydrate. Three methods of treating this mother-liquor are proposed: (1) It is to be boiled down to dryness, and the residuum heated "until one equivalent of sulphur is expelled from it, and only monosulphide of strontium remains." This monosulphide is then to be treated by water for the obtainment of more strontium hydrate and more mother-liquor. (2) The strontium sulphhydrate of the mother-liquor is to be decomposed by sodium sulphate. The resulting strontium sulphate is to be treated as already described, and the solution of sodium sulphhydrate obtained at the same time is to be concentrated until it will crystallise on cooling. (3) The mother-liquor is to be treated by magnesium sulphate, the products being strontium sulphate, magnesium hydrate, and sulphuretted hydrogen.

*Improvements in the Construction of Apparatus for the Manufacture of Sulphurous Acid.* C. A. Allison, London. Communicated by the National Chemical Machine and Manufacturing Company, Newark, U.S.A. Eng. Pat. 4337, Sept. 11, 1883.

THIS invention relates to apparatus for the absorption of sulphurous acid gas by water. The apparatus described is a tall "box" formed of "two-inch yellow pine planks bolted together," and furnished interiorly with an arrangement of horizontal wooden shelves. Water enters at the top of the box, flowing over all the shelves successively, and SO<sub>2</sub> enters at the bottom of the box.

*An Improved Process for Extracting Sulphurous Acids from the Fumes of Furnaces, Ovens, and such.* E. A. Brydges, Berlin. Communicated by E. Brydges, Berlin. Communicated by E. Hänisch and Dr. M. Schröder, Rosdzin, Germany. Eng. Pat. 2621, May 26, 1883.

THE author of this invention claims that it will permit the manufacture of sulphuric acid economically from the sulphurous acid contained in furnace gases. The furnace gases are to be cooled, and then washed with cold water, in a special apparatus, of which a detailed drawing is given. "The concentration of the solution of sulphurous acid so obtained depends on the quantity of SO<sub>2</sub> contained in the furnace gases. With gases containing 1 per cent. SO<sub>2</sub>, 1 cubic metre of water absorbs 3 to 4 kilos. SO<sub>2</sub>. With gases containing 2½ per cent. SO<sub>2</sub>, 8 to 10 kilos. are absorbed." The solution of SO<sub>2</sub> is heated to 100° C., and is then converted into spray, and through this spray a current of hot air is passed. This causes the solution to give up its SO<sub>2</sub>, which passes off mixed with four times its volume of air, the mixture being richer both in SO<sub>2</sub> and in oxygen, than the gases ordinarily supplied to vitriol chambers. The waste heat of the furnace gases is used to heat the solution of SO<sub>2</sub>.

*Improvements in the Manufacture of Sulphite of Lime and of other Earthy or Alkaline Bases.* R. Powell, Liverpool. Eng. Pat. 2502, May 19, 1883. Not proceeded with.

THE method for the manufacture of sulphite of lime proposed by the author of this invention consists in "withdrawing one atom of oxygen from sulphate of lime by intimately intermingling the sulphate of lime with the necessary portion of carbon or sulphur," and heating the mixture in a closed or partially-closed vessel.

*Improvements in Deplacé's Apparatus for the Concentration of Sulphuric Acid.* Gustav Deplacé, Namur. Ger. Pat. 23159, December 31, 1882.

THE long flat boiler *a*, with rounded ends, is provided with a cover vaulted in several divisions. These vaults, or domes, are capped by bell-shaped receivers, *b*<sub>1</sub>, *b*<sub>2</sub>, *b*<sub>3</sub>,

and  $b_4$ , which, from being cooled on their exterior serve as condensing heads. The acid which condenses upon and trickles down the interior of these caps serves to secure the junction between the caps and their exit openings, by which it passes into and is conveyed away by the tubes  $c_1$ ,  $c_2$ ,  $c_3$ , and  $c_4$ , blown on to the side. In the condenser head  $b_3$ , which is situated nearest to the acid supply cock C, water alone collects. This is run off by  $c_4$ . The distillate in the condenser head  $b_2$  contains, besides much water, a little distilled acid. This distillate is returned to the lead chambers. By the time that the acid passing through the apparatus has arrived at  $b_1$  and  $b_2$  its concentration has become such that a very strong acid distils into and is condensed in  $b_1$  and  $b_2$ ; from thence it flows through  $c_1$ ,  $c_2$ , and  $c_3$  into the supply funnel  $e$  and together with fresh chamber acid is again passed through the apparatus. The concentrated acid is run off at  $d$ . The temperature of the acid in the boiler

coke towers, down which are flowing the liquors, containing iron as sesquioxide. These liquors, when saturated with sulphuretted hydrogen, are mixed with a fresh quantity until potassium sulphocyanide, producing no red coloration, shows that the reduction is complete. Separated sulphur is removed from the liquor by filtration. The product obtained by the evaporation of the filtrate is pure white in appearance, and does not become of a yellow colour even after prolonged contact with the atmosphere. This is owing to the formation of the double sulphate of ferrous oxide and magnesia.—W. D. B.

*Process for Obtaining Preparations of Aluminium Acetate.* Jul. Atbenstaedt, Bad Essen, near Osna-brück. Ger. Pat. 23444, Jan. 10, 1883.

BASIC aluminium acetate of the formula—

is controlled by the two pyrometers  $f$ . The boiler is placed directly over the furnace, and it is advisable to make the bottom of corrugated platinum. The employment of corrugated platinum sheet has the double advantage of strength combined with thinness, and of ready expansion and contraction proportionate to the variations of temperature. B is the inflow tube for the cooling water. The latter flows from B through the tubes  $h$ , which can be connected or shut off by the tap  $r$ , enters the cooling vessels K between their sides, and those of the condenser heads  $b_1$ ,  $b_2$ ,  $b_3$ , and  $b_4$  and finally runs away through  $i$  and F.—W. D. B.

*Process and Apparatus for the Preparation of Sulphites of the Alkalies for the Treatment of Wood and Fibrous Materials.* F. C. Kudelski, Tiffanges, Vendée. Ger. Pat. 23586, August 11, 1882.

THROUGH solutions of sodium, potassium, magnesium, or ammonium sulphate, to which calcium hydrate or carbonate has previously been added, sulphurous acid is conducted. Sulphites or bisulphites are thereby formed and calcium sulphate is precipitated. The apparatus consists of a series of vats provided with agitators, the sulphurous acid and the liquors being caused to stream through the vats in opposite directions.—W. D. B.

*Process for the Manufacture of Chloride of Lime.* Carl Opl, Hruschau. Ger. Pat. 23587, Oct. 14, 1882.

By pressure or suction, chlorine gas, previously freed from aqueous vapour, carbonic acid, and hydrochloric acid, by traversing thin layers of unslaked lime, is caused to permeate porous calcium hydrate built up in layers of convenient thickness in chambers with false bottoms. The absorption is complete when chlorine makes its appearance under the false bottoms. During the absorption the chambers are kept cool from without by means of water.—W. D. B.

*Process for Rendering the Presence of Iron Non-Detrimental to Aluminium Sulphate Neutralised with Magnesia.* F. Lienau, Uerdigen. Ger. Pat. 23493, Aug. 24, 1882. Addition to 21346, June 23, 1882.

THE sesquioxide of iron is reduced to monoxide by means of sulphuretted hydrogen passed upwards through

may be separated, from concentrated solutions, in the amorphous, soluble modification, by dissolving in such solutions, heated to a temperature of from  $30^\circ$  to  $35^\circ$  C. a sufficient quantity of sodium sulphate under prolonged agitation. The precipitation under such circumstances of the above basic acetate depends upon its insolubility in a concentrated solution of sodium sulphate. This compound can also be prepared by the double decomposition of aluminium sulphate and sodium acetate. For this end the quantity of water is so regulated that a sufficiently concentrated solution of sodium sulphate is produced to cause the separation of the amorphous basic acetate as a layer of the consistency of honey, at the surface of the liquid, which had been rapidly heated to from  $30^\circ$  to  $35^\circ$  C. The amorphous preparation soon becomes crystalline, and insoluble in water. In this form it occurs in commerce. When freshly prepared it dissolves in water, and the solution, to which a little acetic acid has been added, is well suited for dyeing operations. By mixing the crude amorphous product with lime a dry mass is formed, from which a solution of aluminium acetate is readily obtained by the addition of dilute sulphuric acid, the lime being separated as sulphate.—W. D. B.

*Process for the Manufacture of Sulphate of Soda free from Iron.* B. Schmaltz and Carl Loewig, Schönebeck. Ger. Pat. 23378, January 9, 1883.

TO a hot mixed solution of kieserite and sodium chloride, of about  $20^\circ$  B., is added the solution obtained by causing concentrated hydrochloric acid to flow over sulphate of soda. The whole is filtered by means of rock salt. From the filtrate sodium sulphate, uncontaminated by iron, crystallises out. By the evaporation of the mother-liquor there is obtained a less hydrated Glauber's salt, contaminated with magnesium chloride. This crop of sodium sulphate is drained and employed in the saturation of the kieserite solution for subsequent operations.—W. D. B.

*Process for the Preparation of Barium and Strontium Compounds.* F. Muck, Bochum. Ger. Pat. 23372, Nov. 10, 1882.

FOR the preparation of barium and strontium compounds from mixtures of the corresponding chlorides with other chlorides—particularly those of sodium, calcium, and magnesium—the concentrated mother-liquor containing such a mixture is treated with a hot satu-

rated solution of sodium chloride. This dissolves all the chlorides with the exception of the sodium chloride derived from the mother-liquor. The sodium chloride liquor is repeatedly employed, and when sufficiently enriched is set aside to cool, whereby the chlorides of barium and strontium are caused to crystallise out. The mutual separation of these two compounds is effected by mixing their cold saturated solution with not much more than twice its volume of hydrochloric acid. Thereby the barium chloride is almost completely precipitated.—W. D. B.

*Process for the Purification of Solutions of Metallic Salts Contaminated with Iron.* F. C. Glaser, Berlin. Ger. Pat. 3375, Nov. 21, 1882.

The solution of aluminium sulphate, which must contain the iron as sesquioxide, is rendered feebly alkaline, and mixed with an excess of stannic acid. The precipitate produced soon subsides, and contains the iron. The supernatant solution is drawn off, the precipitate is washed, and then extracted with dilute sulphuric acid. The iron dissolves for the most part, and the residual stannic acid may be employed for repeated operations. Antimonious and antimonie acids behave like stannic acid.—W. D. B.

*Method for the Manufacture of Alkaline Hydrates and Carbonates from the Corresponding Chlorides.* La Société Anonyme Lorraine Industrielle, Nancy. Ger. Pat. 23791, Aug. 25, 1882.

THE product obtained by the action of lead oxide upon the alkaline chlorides is treated with alcohol; the solution is filtered, and the alcohol recovered from it by distillation. The residue from the alcoholic solution is freed from alcohol by the addition of a small quantity of water, and then evaporated to dryness; or the alcoholic extract is treated with carbonic acid, whereby the potash is separated as carbonate, which is filtered off. The alcoholic filtrate is again used in the process without undergoing any purification. The preparation of sodium carbonate is a little more complicated, inasmuch as this salt is slightly soluble in alcohol. The alcohol coming from the filters is therefore treated with lime, whereby the carbonate is converted into hydrate which remains in solution. The lead chloride obtained in the process is dissolved in hot water, and the lead precipitated with white pig-iron, to be again converted into oxide.—F. M.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*Process for the Ornamentation of Porcelain Articles with Dull Gilding to Resemble Chasing.* Gebrüder Schoenau, Huttensteinach. Ger. Pat. 23451, October 19, 1882.

THE plaster-of-paris moulds for these articles are cast upon models with ornamentation, possessing a finely-granular surface, either intuse or elevated. The ornamentation of the porcelain articles will therefore likewise possess a granular surface. After the biscuit-baking, the granular portions are brushed with oil, and the objects glazed by dipping, whereby the oiled surfaces are left untouched. These are now dusted with dry pulverised enamel, which, by gentle rubbing, is easily caused to enter the hollows of the ornamentation. After being baked, the objects are gilded, and now, by the difference between the gilding of the plain and that of the roughened or granular surfaces, the appearance is suggestive of chased gold.—W. D. B.

*Process for the Production on Glass of Tinted Transparent Designs on Deadened Surfaces.* S. Reich and Company, Vienna and Berlin. Ger. Pat. 23351, Nov. 5, 1882. Addition to 21540, July 18, 1882.

THE whole surface of the object is first deadened, and the design painted thereon with the compound specified

in the original patent, but, moreover, containing the necessary colouring matter. By the fluxing of this mixture transparent coloured designs are produced on a dead ground.—W. D. B.

*Method for the Manufacture of Porous Earthenware from a Mixture of Clay and Naphthalene.* Siegfried Stein, Bonn. Ger. Pat. 23947, Dec. 1, 1882.

THE naphthalene is mixed with water or dissolved in a suitable manner, and in this form well incorporated with the clay. The articles formed from this mixture are dried and then, in order to recover the naphthalene, heated to a temperature at which the latter is melted out or volatilised, whereupon they are burned in the usual manner. The burned articles show an even porosity, and as the naphthalene does not leave any ash the pores cannot inside be covered with a more fusible mass, which would partly fill up the pores, and thus make the articles less capable of resisting changes of temperature.—F. M.

*Method for the Manufacture of White Lime Alumina Glass.* Otto Korschelt, Dresden. Ger. Pat. 24227, Oct. 4, 1882.

THE glass mixture contains no alkalis, and is composed of from 8 to 10 parts of alumina, 55 to 67 parts of silica, and 35 to 15 (?) parts of lime (magnesia or baryta). The alumina is used in the shape of clay, as free from iron as possible, or as felspar-like rock rich in alumina. The lime employed may either carbonate or hydrate. The addition of silica is only necessary in case the clay employed does not already contain a sufficient quantity of it. The mixture is melted in a continuous Siemens furnace. A clear, homogeneous, strongly-refractive glass is obtained, when from 5 to 7 per cent. of the above mixture are replaced by the same quantity of soda.—F. M.

*Method for the Manufacture of Porcelain Presenting a Marble-like Appearance.* Morgenroth and Company, Gotha. Ger. Pat. 24153, Jan. 12, 1883.

THE white and coloured porcelain masses are dried till they can easily be granulated, whereupon they are passed through a wide mesh sieve. They are then moistened with a mixture of petroleum and rape oil, and mixed. The mixture is pressed in steel moulds.—F. M.

## IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

*Improvements in the Manufacture of Artificial Stone.* F. H. F. Engel, Hamburg. Communicated by E. Murjahn, Hamburg. Eng. Pat. 2535, May 21, 1883.

“THIS invention has for its object the manufacture of artificial stone out of clay and peat, which stone can be made of different degrees of hardness. The process of manufacture consists of mixing in a damp state clay and peat (which latter must be pulverised in certain proportional quantities), and by forming out of such mixture stones, blocks, ornaments, or other objects, which after being dried to a certain degree are burned in kilns, or otherwise, like common bricks or pottery. According to the proportion of peat included in the mixture, the material produced varies in density, weight, and hardness. One portion of peat and two portions of clay produce a material that may be usefully employed in the construction of walls for buildings. As the weight of this improved artificial stone is less than that of common bricks, the foundation need not be so strong as would be required if the latter were used.”

*An Improved Metallic Cement.* J. McConnell, Ballymena. Eng. Pat. 2845, June 7, 1883. Not proceeded with.

FINELY-DIVIDED “black antimony” and finely-divided plumbago are intimately mixed together, and the mixture

is then added to and well stirred with molten sulphur. The resulting cement is said to be "particularly adapted for closing holes and joints in cast or malleable iron, as also for cementing metal into stonework and uniting the joints of gas and water pipes, as well as of steam piping where the temperature is not higher than the melting point of the cement itself."

*Method for Utilising Silicious Earths and Rocks in the Manufacture of Cements, for the Purpose of Imparting to them Hydraulic Properties.* Johann Bielenberg, Chemnitz. Ger. Pat. 24038, Nov. 28, 1882.

SILICIOUS earths and rocks such as argillaceous porphyrite, slate, sand-stone, and clay, or even mud from rivers and the sea, are ignited and then exposed to the action of sulphurous acid. These materials after such treatment attain, in combination with lime, hydraulic properties, and thus resemble the Trass, Puzzolane and Santorine earths, which are used in the manufacture of hydraulic cements. The silicious materials which are to be ignited are mixed with coal and acted upon during the process of ignition by sulphurous acid produced from sulphur, which is, together with coal, contained in pipes placed in the draught-holes of the furnace.—F. M.

*Method for the Manufacture of White Cement suitable for making Casts.* C. Haintzel, Lüneburg. Ger. Pat. 23205, Sept. 17, 1882.

For the preparation of a cement, which with water does not become hard, but which with a silicate solution solidifies to a hard mass, pure chalk is mixed with ground quartz, the mixture being formed into tiles which are burned at a white heat. The ground product is made up with a silicate into a thin paste and cast into moulds.—F. M.

## X.—METALLURGY, MINING, Etc.

*On Metallic Alloys.* Dingl. Polyt. Journ. 250, 30.

J. DEPIERRE and P. SPIRAL, in the *Berichte der Oesterreichischen Chemischen Gesellschaft*, 1883, p. 45, publish a paper on the "Composition of Rollers used in Printworks." According to Hauvel (*Technologiste*, 1878, p. 369) a bronze of medium hardness and of the following

authors could only obtain the following analyses of doctors:—

	Copper.	Zinc.	Tin.
Yellow French doctors analysed by Salvetat .....	78.75	12.50	8.75
Yellow English doctors analysed by Bertbier .....	80.50	10.50	8.00
Yellow German doctors analysed by Elsner .....	85.80	9.80	4.90

According to the researches of the authors three classes are to be distinguished: (1) Copper with 95 to 100 per cent. of copper; (2) brass with, say, 60 per cent. of copper and 40 per cent. of zinc; (3) alloys. In Table I. the physical properties of the samples examined are stated, and the remark is made that in printing rollers, where the hardness of the metal plays a pretty important role, the chemical composition alone does not fully express all the peculiarities of the metal. These also depend on the method of hardening employed, also the manner in which the roller has been tempered. The chemical composition of the samples is seen in

TABLE II.

	No. of Samples.	Copper.	Tin.	Lead.	Zinc.	Remarks.

24	Yellow	2	—	—	—	—
25	(Greyish Yellow)	3	—	—	—	Attacked by colours.

composition is most suitable: Copper, 86; tin, 14; zinc, 2. Rendell obtained the following numbers on analysing an English roller: Copper, 78.3; tin, 5.6; zinc, 15.8. Although the above composition yields a hard, fine-grained alloy, yet no doubt it would be very easily attacked by the colours employed in printing. The

Besides the red copper alloys those containing 25 to 30 per cent. of zinc and 70 to 75 per cent. of copper will be found very suitable for printing. Lead, even in quantities of 0.5 per cent., acts injuriously, and all samples containing lead exhibited signs of blistering. In no sample could the presence of phosphorus be proved, and

yet the authors are of the opinion that rollers made of copper, containing from 1 to 2 per cent. of phosphorus, would work exceedingly well, both as regards resistance to chemicals and with respect to hardness, fineness of grain, regularity, and wear. Also an addition of 1 per cent. of phosphorus is recommended for the varieties of brass containing from 30 to 35 per cent. of zinc.—H. S. P.

*An Improved Method or Process of Enamelling Cast Iron.* G. J. Rhodes, Wolverhampton. Eng. Pat. 2315, May 7, 1883.

"In applying enamels directly to the surface of cast iron as heretofore practised, when the enamel, which is applied either in a liquid state or in the form of powder, is being fired to produce a glazed surface, the said surface becomes covered with bubbles or blisters caused by the expulsion, under the action of heat in the muffle, of the gases imprisoned in the iron, thereby impairing the appearance of the enamel, and rendering it useless as a protection to the iron from rust." To prevent the formation of these bubbles or blisters, the author of this invention "expels nearly the whole of the gas from the pores of the iron, and partially fills the said pores with oxide of iron," by subjecting the iron to the Bower-Barff process before proceeding to enamel it.

*A New or Improved Process for the Extracting of Silver, Lead, Copper, and Zinc from Bluestone and other Mixed Ores, and apparatus employed therein.* J. Cross and G. I. J. Wells, Widnes. Eng. Pat. 2386. May 10, 1883.

"BLUESTONE" or others similar "mixed ore" is first digested, without being previously calcined, in hot hydrochloric acid, the lead contained in the ore being thereby converted into chloride. The liquor drawn off from the stone tanks in which this operation is performed is partly but not completely neutralised by lime, is then "well boiled," and is then filtered while hot. On cooling, the filtered liquor deposits nearly all its lead as crystals of chloride. Any lead or silver left in the mother-liquor is precipitated by "yellow liquor" from alkali waste. Or, instead of the greater part of the lead being allowed to crystallise as chloride, and the remainder being precipitated as sulphide, the whole of it is precipitated in the metallic state by the action upon the solution containing it of scrap iron. The residue left in the stone tanks in which the raw ore was treated by hot hydrochloric acid is washed, dried, and then calcined to drive off its sulphur, which is said to go off from it much more readily than from ore from which the lead originally contained therein has not been removed before calcination. The calcined ore is then treated by hydrochloric acid, which dissolves its zinc, copper, and silver. The solution so obtained is neutralised by lime or limestone or chalk, filtered, and then treated by just enough yellow liquor to precipitate as sulphides its silver and copper. These are separated from their mother-liquor by means of a filter press, and the filtrate is then treated by more yellow liquor, which precipitates as sulphide the zinc at first contained in it. Or the zinc of this liquor can be precipitated as oxide by boiling the liquor with lime.

*Improvements in the Manufacture of Fluxes or Material used in the Preparation of Plates to be Coated with Tin, Zinc and other Metals.* H. F. Taylor, Neath and Briton Ferry, and G. Leghorn, Tividale. Eng. Pat. 2012, 1883.

This invention seems to consist in neutralising, by means of "lime or chalk or magnesia or the carbonates of any of the alkaline earths," solution of chloride of zinc which is to be used for preparing iron plates which are to be coated with tin.

*An Improved Method or Process of Extracting or Separating Iron from Solutions containing the same.* G. W. von Nawrocki, Berlin. Communicated by Loewig and Company, Goldschmieden, Germany. Eng. Pat. 2506, May 19, 1883.

THESE improvements consist in "the extraction or separation, by means of electricity, of iron from solutions of metallic salts, such as sulphate of soda or sulphate of alumina." When treating solutions of sulphates, the anode is to be of lead, "but silver is preferable for metallic chlorides." "The separation of the iron will not take place unless the production of oxygen at the anode can be almost entirely prevented. This can be effected either by using an anode with a large surface or by causing as much resistance as possible to be offered to the passage of the electric current at the anode. It is most advantageous, however, to combine both these methods." There must be no free acid in the solutions treated.

*A New or Improved Process for Producing a Protecting Coating of Rust on Cast Iron, Wrought Iron, or Steel.* L. A. Groth, London. Communicated by E. Nicolaus, Lauchhammer, Germany. Eng. Pat., May 31, 1883.

A COATING of oxide is to be produced on articles of cast iron, wrought iron, or steel by first annealing them, if necessary, then "pickling" them in dilute sulphuric or hydrochloric acid, and then, after a mechanical scouring, "so laying on a dilute inorganic acid (about 1 part acid to 5 parts of water) that the surface is covered with a very thin coating of the liquid." The articles are then to be allowed to dry completely, and then, after having been well "brushed or rubbed with clean rags," are to be again covered with a thin coating of dilute acid. After having again been allowed to dry, and "the rust which is not fixed" having been again removed by brushing or rubbing, they are to be painted over with linseed oil, and then dried in an oven.

*Improvements in the Treatment of Phosphatic Slags for the Production of Phosphates of Earths and Manganiferous Oxides of Iron.* C. Pieper, Berlin. Communicated by C. Scheibler, Berlin. Eng. Pat. 2435, May 15, 1883.

THIS invention consists in a modification of one part of the process of treating phosphatic slags which is the subject of the patents No. 5835 of 1822 and No. 1602 of 1883. The process described in the specifications of those patents begins with the reduction of the slags to a fine powder, which powder is afterwards roasted in an oxidising flame in order to convert the MnO and FeO of the slags into higher oxides. The inventor has since found that the reduction of the slags to powder before calcining them may be dispensed with. By his present invention "the slags are roasted in lumps of about a fist's thickness in an oxidising flame, and the so roasted lumps are then exposed to the action of water or steam. This has the effect that the caustic lime contained in the slag combines with the water to form hydrate of lime, and the reaction makes the lumps break up into fine powder."

*Dephosphorisation of Iron at a Red Heat.* Paul Keil, Kattowitz. Ger. Pat. 23244, Jan. 31, 1883.

THE pig iron is granulated and heated with an alkaline carbonate to a red heat. The mixture, which is contained in iron vessels, is agitated during the process.—F.M.

*Process for the Separation of Iron from Solutions obtained by the Extraction of Zinciferous Pyrites Residues.* Actiengesellschaft Georg Egestorff's Salzwerke, Linden. Ger. Pat. 23712, Feb. 22, 1883.

BARIUM or calcium carbonate is added to the solution obtained by the extraction of zinciferous pyrites residues, and air blown through the liquor. The iron is speedily

precipitated, and there is produced, on the one hand, iron, free from zinc, suitable for blast furnace operations; on the other hand, zinc salts, free from iron, are obtained.—W. D. B.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*Improved Methods or Processes for Extracting Glycerine from Fatty Substances.* W. R. Lake, London. Communicated by E. O. Banjard, Auberoillier, France.

This invention consists in digesting fatty substances with about 30 per cent. of their volume of water and "two or three thousandths of their weight of pure metallic zinc," very finely divided, under a pressure of "about 150lb."

*Improvements in the Manufacture of Soap.* E. A. Brydges, Berlin. Communicated by F. O. Spielhagen, Berlin. Eng. Pat. 2707, May 31, 1883. Not proceeded with.

The author of this invention manufactures a "petroleum soap" as follows: "About 33 per cent. petroleum is mixed with about 1 per cent. spirit; about 66 per cent. fat or oil" is heated to 45° C.; the fat or oil so treated is then added to the "mixture of petroleum and spirit," and the whole well stirred. To the mixture so obtained is then added "about 50 per cent. of 40 per cent. caustic lye of soda, 25 per cent. of water glass, and 25 per cent. of silicate of alumina, infusorial earth or similar substance, and the whole mixture briskly stirred until it has grown so thick and solid that it can only be worked with great difficulty." It is then further manipulated "with forked sticks" until "it begins to steam, and is again converted into a fluid condition." It is then poured into moulds, in which it solidifies on cooling.

*Improvements in the Extraction of Gelatin, Fat, and Similar Substances from Bones, Hide, Fish, and other Animal Matter.* C. D. Ekman, London. Eng. Pat. 2680, May 30, 1883.

"THE object of this invention is to extract from bones, hides, fish, or other substances of animal origin, their useful constituents (such as gelatin and fat) in such manner as to obtain products of quality and colour superior to those obtained by the ordinary methods, and the invention consists in boiling the raw materials under pressure in solutions containing sulphurous acid with or without a base or alkali." It is preferred to use solution of bisulphite of magnesium, of such strength as to contain "1 per cent. of sulphurous acid." The operation is performed in vessels lined with lead. When the chief object is to obtain gelatin, a pressure of 5lb. per square inch is employed; but "when the production of fat is the main object in view, then the pressure employed may exceed 10lb. to the square inch."

*The Application of Oxide of Zinc or Zinc-Dust in Assisting the Saponification of Fats by Water.* C. F. E. Poullam, E. F. Michaud, and E. N. Michaud, Paris. Ger. Pat. 23213, Nov. 2, 1882.

THE fat are heated under increased pressure in an autoclave for a considerable time with water and from 0.2 to 0.66 per cent. of their weight of oxide of zinc. The oxide of zinc may be applied either in the form of zinc-white or that of zinc-dust. It is claimed that this addition hastens the saponification of the fats and prevents discoloration of the fatty acids.—W. D. B.

*Improvements in the Manufacture of Lubricating Oil.* N. C. de Kroeber, Baku, Russia. Eng. Pat. 2123, 1883.

IN the process claimed as an invention in this patent "the residue from the distillation of petroleum—that is to say, what is left after the removal of the light and

burning oil"—is first agitated with about 10 per cent. of its weight of sulphuric acid "of a strength of about 66° Reaumur." The oil and sulphuric acid are then separated, and the former is then treated by lime or by an alkali.

*Improvements in Refining and Decolouring Soap made from Cotton-seed Oil or from other Oil containing Extractive Colouring Matter, and in Valuable Products obtained therefrom.* J. Longmore, Liverpool. Eng. Pat. 2456, May 16, 1883. Not proceeded with.

SOAP is to be made from "refined or crude cotton-seed oil, or other oils containing extractive colouring matter," by "adding sufficient caustic lye to produce saponification in the usual manner," and the soap so formed is then to be separated, instead of by salt, "by the further addition of caustic alkali." The resulting lye, "which contains nearly all the colouring matter in solution," is then drawn off, and water is added until the soap "closes." The soap is now again separated by means of caustic lye, treatment alternately by water and by caustic lye being continued until the removal of colouring matter has been accomplished as far as necessary. The coloured lyes are to be treated by carbonic or other acid to separate their colouring matter, which is then to be "utilised as a dye-stuff."

## XII.—PAINTS, VARNISHES, AND RESINS.

*Composition of Matter to be used as a Paint or Dye.* Alexander Melville Clark. A communication from the Leeds Manufacturing Company, Brooklyn, New York, U.S.A. Eng. Pat. 1683, April 3, 1883. Provisional protection only.

THE composition consists of a mixture of 5 parts of picric acid, 3 parts flavine, and 12 parts nitric acid of 36° B. This mixture is boiled to dryness, and is then said to produce "an unusually fast and permanent colour," which the inventor has named "echurine." By varying the proportions of the three constituents, different shades, varying from salmon colour to greenish yellow, are formed, and are all included in the designation "echurine." The supposed nature of the action of nitric acid upon the two other components is stated in the provisional specification.—R. M.

## XIV.—AGRICULTURE, MANURES, Etc.

*Improvements in Artificial Fertilisers, and in Methods of Manufacturing the same.* J. R. Young, junior, Norfolk, Virginia, U.S.A. Eng. Pat. 2691, May 30, 1883.

NIGHT-SOIL is to be mixed with either fish-scrap, guano, or a native phosphate, and the mixture treated by strong sulphuric acid. Besides fixing the ammonia and rendering soluble the phosphates of the materials used, some of the sulphuric acid is decolourised to SO<sub>2</sub>, and this SO<sub>2</sub> is said to deodorise the night-soil.

## XV.—SUGAR, GUMS, STARCHES, Etc.

*A New or Improved Method and Composition for Removing Incrustation from Vessels and Apparatus employed in Sugar Manufacture.* R. de Martino, Milan, Italy. Eng. Pat. 2475, June 2, 1883. Not proceeded with.

"FOR this purpose I form a compound consisting of sal-ammoniac with about 35 per cent. of powdered gall nuts and from 20 to 30 per cent. of sumach. I introduce this compound with water into the vessel that is to be cleansed, and keep the mixture boiling, by steam heat or otherwise, for about 10 hours, or longer if necessary. The incrustation thus becomes detached and divided into small fragments, which can be removed."

*Improvements in the Manufacture of Sugar, and in Apparatus therefor.* J. Görz, Berlin. Eng. Pat. 2427, May 12, 1883.

"ACCORDING to the said invention the syrup, molasses, or other liquid is heated in a vacuum by steam at a low temperature until it forms a concentrated liquor which, after boiling for a short length of time in a vessel with or without the presence of air, is subjected to the action of the electric current. This current is allowed to pass for some time through the liquid mass, which is subsequently left to settle, when, providing the temperature does not exceed 30° C., nearly the whole of the sugar contained in the said mass will precipitate in the form of crystals, which are afterwards collected in the usual manner. The remaining sugar is extracted from the liquor by reboiling and again passing an electric current through the mass, the process being repeated until the liquid mass is thoroughly free from sugar."

*Improvements in the Manufacture of Refined Sugar, and in Apparatus to be used therein.* J. Allen, Stepney. Eng. Pat. 2750, June 2, 1883.

"THE ordinary method of refining raw sugar is to dissolve it in hot water, separate mechanical impurities from it by filtration, decolorise by passing it through animal charcoal, and concentrate in the vacuum pan to recrystallise the sugar. This process of purifying the raw sugar is costly, as it requires a large plant with its attendant expenses, and the granulation of the sugar in the vacuum pan requires great skill and care, particularly the formation of the first grains, the ultimate result depending entirely on the proper formation of the first granulation. Attempts have been made to accelerate the formation of grain by the introduction of grain sugar into the vacuum pan, either before the boiling operation or between successive boiling operations, but with uncertain and unsatisfactory results, as no provision existed for maintaining the vacuum at the moment of such introduction, and consequently the boiling was liable to cease at a moment when it was essential to maintain it." The author of this invention describes an arrangement of apparatus by which grain sugar can be introduced into the vacuum pan without breaking the vacuum therein, and in such wise that such grain sugar "is immediately disseminated evenly throughout the liquor by the ebullition of the liquor itself, and does not fall in a mass to the bottom of the pan, or gather in clots, as it would be liable to do were the vacuum broken." He claims that "if raw sugar is thus introduced into the vacuum pan, the ordinary method of refining may be dispensed with," as regards the raw sugar so introduced, "as the liquor in the pan will rapidly remove" the impurities of this raw sugar, "and, when sufficiently concentrated, will deposit pure sugar on the grains, the impurities being subsequently removed with the syrup by means of draining or centrifugal action."

*Improvements in the Manufacture of Starch.* J. Polson and J. M. Harley, Paisley. Eng. Pat. 2703, May 31, 1883.

THIS invention has reference "not only to starch used for ordinary household or manufacturing purposes, but also to starch used for edible purposes, such as is generally known as 'corn-flour,' or 'prepared corn.'" The invention consists in drying the starch "in a stove whose atmosphere is charged with moisture or steam." This method of drying is said to render the starch "mellow, and more free from that peculiar odour and taste" said to result from the old methods of drying starch.

*Improvements in the Manufacture of Elastic Waterproof Compounds.* W. Burnham, Chicago, U.S.A. Eng. Pat. 2657, May 29, 1883.

THIS invention "is based upon the adhesiveness and insolubility in water of the sap of the mangrove tree, known in Columbia as cativo." By "combining this sap

with caoutchouc in variable proportions, permanently elastic waterproof compounds" are obtained. At ordinary temperature, "cativo" is semi-solid, but it becomes fluid at 130° F. It may be mixed with caoutchouc, "either by using appropriate solvents, such as bisulphide of carbon or naphtha, or by the employment of hot kneading rolls, by means of which the mixture is effected mechanically." In the latter case, the temperature is elevated until the mixture acquires the desired degree of plasticity. "Vulcanised" products may be obtained by kneading mixtures of cativo, caoutchouc, sulphur, or metallic sulphides and oxides. Waterproof varnishes may be made by "dissolving the cativo and caoutchouc in any desired proportion—for example, three parts of cativo to one of caoutchouc—in bisulphide of carbon, naphtha, or other solvent, to which may be added linseed oil, tar, or asphalt, or either of the ingredients ordinarily employed in the manufacture of varnishes from caoutchouc."

*Method for the Separation of Non-Saccharine Substances from Beet-root Juice.* Rudolph Bergreen, Reitzsch-bei-Bitterfeld. Ger. Pat. 23603, Dec. 12, 1882.

PREVIOUS to the treatment with lime, basic magnesium sulphite is added to the juice. The liquor having been warmed, the separation is completed by the addition of a sufficient quantity of colloidal magnesia, lime or sugar-lime. The basic magnesium sulphite is prepared by acting with sulphurous acid on suspended magnesia (obtained by precipitation) at a temperature below boiling heat, or by dissolving precipitated magnesia or magnesium carbonate in neutral or acid magnesium sulphite.—F. M.

*Improvements in the Treatment and Preparation of the substance known as "Gum Tragacanth."* A. C. Duncan, Manchester. Eng. Pat. 1933, 1883.

"To improve its condition and behaviour when used in calico printing and other manufactures," the author of this invention treats gum tragacanth by drying it "slightly," then finely grinding it, and then "roasting or calcining it in hot air, or boiling or frying it in petroleum or other oil or medium" in which it is not soluble.

*The Desiccation of Starch in vacuo.* Louis Maiche, Paris. Ger. Pat. 23355, Dec. 31, 1882.

THE blocks of starch are drained, and partially dried in a drying chest. The brownish skin which forms upon the surface having been removed, the blocks, wrapped in paper, are disposed in layers within a closed vertical cylinder heated by steam, and subjected to the action of a temperature not higher than 25° C., exhaustion being simultaneously effected by means of an air pump. With this very rapid process of desiccation all fermentation or moulding in the interior of the blocks is avoided.

W. D. B.

*Recovery of the Ammonia by Precipitation from the Alcohol used in the Process of Extracting Sugar from Molasses.* H. Stellens, Mühlberg-a.-E. Ger. Pat. 23594, Jan. 13, 1883.

TO the ammoniacal alcohol recovered in the distillation of the lime-sugar compound or the mother-liquors concentrated sulphuric acid is added, whereby, provided a certain degree of concentration is maintained, nearly all ammonia is separated out as crystalline sulphate. When the alcohol contains too much water, only a concentrated solution of ammonium sulphate is obtained. In this case a concentrated solution of potassium sulphate is added to the latter, taking the precaution not to bring it into contact with the alcohol. The solution of potassium-ammonium sulphate thus obtained is then mixed with the supernatant alcohol, whereby potassium-ammonium sulphate is separated in a crystalline condition.—F. M.

**Vacuum Pan with Large Heating Surface and Separate Stage Heating System for Direct and Exhaust Steam.** Franz Wellner, Pilsen, and Hugo Jelinek, Prague. Ger. Pat. 23078, Aug. 10, 1882. Addition to 6958, Feb., 1879.

The pan has a box form, and its bottom is formed by the two slanting sides *g*. The heating chambers of the horizontal steam pipes are divided into two parts by the

transverse wall *PQ*, to enable direct and exhaust steam to be used simultaneously for boiling. An endless-screw *S* is used for removing the last portion of the contents after discharging the pan.—W. M.

**Stage Evaporating Pan.** F. Wellner and H. Jelinek, Vienna. Ger. Pat. 24001, Feb. 3, 1883. Addition to 6958, Feb., 1879.

IN order to increase the heating surface of the vacuum pan for evaporating sugar and salt solutions, while preserving its box form, the heating system is composed of several stages. The vapours from the several stages are aspirated together. The juice is either evaporated separately in each stage or run continuously from the upper to the lower stages by overflow pipes, to be run off from there for further concentration.—W. M.

**Safe for Vacuum and Evaporating Pans.** Herm. Schmidt (of the firm of C. Aug. Schmidt and Sons, Hamburg). Ger. Pat. 23606, Feb. 23, 1883.

IN this safe, which is placed in the dome *D* of the vacuum pan *A* or in the overflow vessel, the steam pipe *d* is bent at the top at right angles and connected to the pipe *c*. This pipe is led in a circle round the inside of

the dome, and increases from the almost square section I. to the section II., and finally the long section III., the area remaining however unaltered. At III., after a complete turn, the pipe *c* opens in the space *C*, from which the steam escapes through the sieve *m*, while any liquor carried along with it falls back through *k*.—W. M.

**Modifications in Hydro-Extractors with Continuous Action.** F. W. Strohbach, Köthen. Ger. Pat. 22725, May 6, 1882.

THIS hydro-extractor, which is to serve chiefly for drying sugar crystals and extracted beetroot slices, consists of a conical basket *c* with a wide central feed-tube *g*. The outside of the casing *a* is furnished with two symmetrical channels *b b*, which surround the latter com-

pletely at the top, but diminish towards the bottom. When the hydro-extractor is working the substance to be extracted rises slowly up the inclined walls of the basket *c*, and when dry falls over the rim of the latter into the channels *b b*, from which it is delivered at the openings *e c*.—F. M.

**Improvements in the Manufacture of Glucose Syrup and Grape Sugar.** Hermann Endemann, Brooklyn, U.S.A. Ger. Pat. 24041, Dec. 24, 1882.

IN order to avoid the considerable quantity of sulphate of lime which is left dissolved in glucose syrup when sulphuric acid has been used in the manufacture, this acid is replaced by phosphoric acid, the lime salt of which is almost completely insoluble. The conversion of starch takes place under pressure, and at a temperature of 140° C., 5 per cent. of orthophosphoric acid on the weight of the dry starch being employed.—W. M.

**Process for Decolorising Crystallised Anhydrous Grape Sugar.** Th. von Korvin-Sakowicz and D. Rosenblum, Warsaw, Russia. Ger. Pat. 24181, Feb. 7, 1883.

THE starch-sugar solution, after neutralisation with chalk, is cooled to 45° C., and treated with permanganate of potassium, 0.2 per cent. on the weight of starch being used, and is filtered from the resulting brown precipitate and the sulphate of lime.—W. M.

**Purification of Beet-Juice and Molasses by means of Soluble Glass.** E. A. Schott, Kreinsen. Ger. Pat. 24129, Nov. 23, 1882.

THE raw beet-juice or molasses is treated with silicate of potash, the amount used being in proportion to the albuminous matter present, nearly neutralised with sulphurous acid, exactly neutralised with sulphuric acid, and finally filtered from the precipitated hydrate of silica.—W. M.

## XVI.—BREWING, WINES, SPIRITS, Etc.

**The Production of Yeast by the Fermentation of Molasses and Grains Saccharified by Means of Acids.** Gustave Claudon and Charles Vigreux, Paris. Ger. Pat. 23329, Oct. 28, 1882.

A MIXTURE of 150kg. of maize saccharified by treatment with an acid, and 2,150kg. of molasses is brought into fermentation by the addition of beer yeast, the whole being maintained at a temperature of 25° C., until the fermentation has attained its maximum. When this is the case, the temperature is reduced, by means of a cold water refrigerator, to 18° C., and kept at that point until the yeast, which began to collect during the more active stages of fermentation, has thoroughly separated. Hereupon the temperature is again raised to from 26° to 27°, and the process rapidly brought to an end.—W. D. B.

*Improvements in the Process for Preparing Mash, Yeast, and Malt-Extract.* H. Gruson, Buckau, near Magdeburg. Ger. Pat. 22621, Nov. 7, 1882.

AN "Excelsior" kibbling mill B, for grinding the substances employed in the moist condition, is interposed between the "Henze" steaming apparatus and the mash-tun F, thus providing an arrangement suitable for the production of yeast. During the disintegration of the potatoes, maize, or cereals fed into B by means of the tube A, the steam-tight cover *s* is kept closed. In the

preparation of yeast material, the green malt is introduced by the funnel B, provided with a rotary toothed cylinder at its lower end, and a steady current of water at 60° C. is supplied by the pipe *v*. The pulpy yeast material collects in the vat E. For the preparation of malt-extract the same manipulation is suitable, but instead of a current of warm water at 60° C. being fed in by *v*, one of cold water is supplied by means of *k*.—W. D. B.

## XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

*Improvements in the Manufacture of Salicylic Acid, producing also Alcoholic Phenates.* William Lloyd Wise. A communication from Dr. W. Hentschel, Dresden. Eng. Pat. 2119, April 26, 1883.

THE inventor has discovered that diphenyl carbonate can be prepared on a manufacturing scale by passing phosgene gas into an aqueous solution of sodium phenolate. This method differs from Kempf's (*Journ. of Prac. Chem.* 4, 404), in which free phenol is used and the operation performed in sealed tubes under pressure. The diphenyl carbonate is decomposed by distillation with sodium hydroxide when salicylic acid and phenol are produced—

By decomposing with sodium methylate or ethylate the phenolic ethers, anisole and phenetole, are produced—

The phenol or phenolic ether distils over, and the sodium salicylate which remains is decomposed by hydrochloric acid.—R. M.

*Paraguay Tea.* A. W. Selliu. Archiv. Pharm. 221, 292. THE author recommends this tea as being very pleasant to the taste, as well as cheaper and less injurious than Chinese teas. The *Ilex Paraguayensis*, the leaves of

which constitute this tea, is common to the mountain woods of Southern Brazil, the Argentine Republic, and Paraguay. It is an evergreen resembling the orange tree in its growth. The green twigs are pulled in April, May, and June, dried over a fire and deprived of their leaves; these are reduced by striking with wooden mallets, packed, and sent into commerce. A tree will yield 35 kilos. of the tea every three years. The total production for Brazil and Paraguay for 1880 was of the estimated value of £65,000.—C. F. C.

## XXI.—EXPLOSIVES, MATCHES, Etc.

*Blasting Cartridges composed of Saltpetre, Sulphur, Wood Charcoal, Bran, and Magnesium Sulphate.* Jean Gemperle, Vienna. Ger. Pat. 23933, Dec. 10, 1882.

SEVENTY-THREE parts by weight of saltpetre and 1 part magnesium sulphate are dissolved in one-third of their weight of boiling water, and to this solution is added 8 parts ground wood charcoal, 8 parts ground bran, and 10 parts sulphur, which components have been previously dried and mixed. The mass is thoroughly stirred and heated to 140° C. for two hours, after which it is placed in a drying apparatus at a temperature of 50° C. for five hours. The dried mass is pressed into cylinders or cartridges. The nitrate of potassium can be replaced by nitrate of sodium when the cartridges are to be used soon after being manufactured.—W. M.

## XXII.—ANALYTICAL CHEMISTRY.

*Titration of Manganese by Means of Potassium Permanganate.* Report Anal. Chem. 1883, 337, and Ber. 18, 3074.

THE solution of manganous chloride precipitated with zinc oxide is added gradually to a solution of 25 to 30 grammes of zinc sulphate, contained in a 500c.c. flask, and previously treated with a known quantity of permanganate solution more than sufficient to determine the quantity of manganese. The mixture is then made up with water to 500c.c., and an aliquot part of the solution filtered through asbestos. The determination of the excess of permanganate is effected by means of a solution of antimonious chloride according to Kessler's method. D. B.

*Qualitative and Quantitative Separation of Bismuth and Copper.* T. Löwe. Zeit. Anal. Chem. 22, 495, and Ber. 18, 3075.

THE salts of copper and bismuth are precipitated by sodium hydroxide in the presence of glycerol, the precipitates being soluble in an excess of the precipitant. From the solution the copper is completely separated as protoxide by grape sugar in the cold, the reaction being ended in the course of a few hours, whilst the alkaline solution of bismuth remains unaltered. The author bases a method for the quantitative separation of copper and bismuth on this reaction.—D. B.

*Estimation of Manganese in presence of Small Quantities of Iron.* W. Diehl. Chem. Industrie 1883, 157, and Ber. 16, 2319.

BOTH metals are precipitated by means of bromine or hydrogen peroxide and an alkaline carbonate, and the mixture of ferric oxide and manganous-manganic oxide is ignited and weighed. The oxides are then dissolved in hydrochloric acid, evaporated to dryness, and the ferric chloride decomposed in the cold with potassium iodide and hydrochloric acid. The free iodine is finally titrated with sodium thiosulphate.—S. Y.

*Estimation of Chlorine in presence of Thiocyanides.* W. Diehl. Chem. Industrie 1883, 157, and Ber. 16, 2319.

A SOLUTION containing the chlorides and thiocyanides is divided into two measured portions. In the one the

chlorine and thioeyanogen are estimated together by titration with silver. In the other the thioeyanogen is removed by precipitation with copper sulphate and sulphurous acid, the solution passed through a dry filter, and the chlorine estimated in an aliquot portion of the filtrate.—S. Y.

## New Books.

**THE ART OF SOAP-MAKING: A Practical Handbook of the Manufacture of Hard and Soft Soaps, Toilet Soaps, etc.** Including many New Processes, and a Chapter on the Recovery of Glycerine from Waste Leys, etc. By ALEXANDER WATT, Author of "Electro-Metallurgy Practically Treated," etc., etc. With numerous Illustrations. London: Crosby Lockwood and Co., 7, Stationers' Hall Court, Ludgate Hill. 1884.

AN Svo volume, bound in cloth, with an introduction of 5 pages, subject-matter covering 241 pages, and alphabetical index of 14 pages. Interspersed with the text are 36 woodcuts. Recipes are given for making various kinds of soaps, and in the closing pages of the work are tables of specific gravities and thermometric scales. Likewise there occur tables of essential oils, fusing and solidifying points of fats and oils, etc. The headings of the various chapters are as follow: Chap. I., Saponification Explained. II., The Soap Factory: its Apparatus and Appliances. III., Materials Used in Soap-Making. IV., Caustic Leys. V., VI., and VII., Manufacture of Hard Soaps. VIII., Making Soap by the Cold Process. IX., Oleic Acid: Soap from Recovered Grease. X. and XI., Cheapened Soaps. XII., Disinfecting Soap. XIII., Saponification under Pressure. XIV., Various Processes. XV. and XVI., Manufacture of Soft Soaps. XVII., XVIII., and XIX., Manufacture of Toilet or Fancy Soaps. XX., Soft Toilet Soaps. XXI., Medicated Soaps. XXII., Miscellaneous Processes. XXIII., Alkalimetry. XXIV., Analysing Soaps. XXV., Purifying of Bleaching Oils and Fats. XXVI., Recovery of Glycerine from Spent Leys. XXVII., Miscellaneous Soaps. XXVIII., Useful Notes and Tables.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1884.

1445 G. Oldfield, Leeds. Improvements in matches for lighting purposes. January 15  
1464 C. D. Abel, London. An improved manufacture of nickel and cobalt from their ores. Communicated by A. Krupp, Bernsdorf, Austria. January 15  
1472 F. Wirth, Frankfort-on-the-Main, Germany. Improvements in the manufacture of the alkaloides of quina. Communicated by Prof. Dr. Giacosa, Turin. January 15  
1485 W. R. Lake, London. Improvements in and relating to the treatment and utilisation of the residuary products of the distillation of spirits and apparatus therefor. Communicated by Dr. G. Baumert, Halle, Germany. Complete specification. January 15  
1486 W. R. Lake, London. Improvements in apparatus for use in the manufacture of sulphuric acid. Communicated by M. A. Walsh, New Jersey, U.S.A. Complete specification. January 15  
1501 F. W. Gerhard, Wolverhampton. Improvements in the manufacture of cements. January 16  
1536 C. R. Bonne, Manchester. Improvements in and apparatus for the purification of brewers' and other yeast. January 16  
1571 A. H. Huth, Kensington. Improvements in the manufacture of compounds of indiarubber, gutta-percha, and like materials. January 16  
1578 W. G. Little, Conisborough. Increasing the illuminating power of ordinary coal gas. January 17  
1629 W. R. Lake, London. An improved method or process of extracting aluminium from substances containing the same. Communicated by F. J. Seymour, Wolcotville, and W. H. Brown, New York, U.S.A. January 17  
1639 G. Valentine, F.C.S., Liverpool. Improved retorts for the production and revivification of animal charcoal from bones. January 18

1670 J. Robertson, Glasgow, and G. A. Bishop, Coatbridge. Improvements in regenerative kilns for burning bricks, pottery, or articles of a similar nature, or for calcining coal, ironstone, limestone, cement, or other substances. January 18  
1693 H. J. Bollmann Condy, Battersea. Improvements in the manufacture of white lead, and of tri-basic acetate of lead employed in the manufacture of white lead and other salts of lead. Complete specification. January 18  
1707 E. W. Harding, Bishop Wearmouth. Improvements in the manufacture of Portland cement. January 18  
1736 E. Brooke, Huddersfield. Improvements in the manufacture of a refractory material to be used for lining furnaces; also to be used in the manufacture of refractory bricks, blocks, tuyers, pipes, and similar articles. January 19  
1737 J. Trevelyan Raynes, Birkenhead. Improvements in calcining kilns and in apparatus therefor. January 19  
1738 R. Stanley and J. Sharratt, Stockingford. Improvement in the manufacture of terra-cotta and other clay goods. January 19  
1823 F. Wirth, Frankfort-on-the-Main. Improvements in the method of and apparatus for preparing and treating oils and other like substances for industrial purposes. Communicated by L. Starck, Mayence, Germany. January 21  
1834 J. S. Rigby, Widnes. An improved apparatus for the manufacture of white lead. January 21  
1843 J. C. W. Stanley, London. Improvements in the treatment of certain deposits for the purpose of recovering nitrogenous matters therefrom. January 21  
1857 F. Wirth, Frankfort-on-the-Main. Improvements in the method of preparing and using tanning substances. Communicated by L. Starck, Mayence, Germany. January 21  
1864 W. P. Thompson, Liverpool. An improved process for mixing with earthy matter and for consuming as fuel petroleum or other hydrocarbons, and apparatus for carrying the same into effect. Communicated by J. Leede, Washington, U.S.A., and G. H. Ouray, Florence, Arizona, U.S.A. Jan. 22  
1870 W. J. Grass, West Hartlepool. Tanning hides, called plutonic tanning. Communicated by W. Hassler, Hogsby and Staby, Sweden. January 22  
1881 J. H. Johnson, London. Improvements in the manufacture of Portland cement. Communicated by R. Whitman Lesley and J. M. Wilcox, Philadelphia, U.S.A. January 22  
1889 E. Askew Bath, Sketty. An improved process of treating "cotton (or like) waste" (used by engineers and others) for the reutilisation of the same, and of oleaginous or fatty matters adhering thereto. January 22  
1890 J. Harrison, Battersea. Improvements in the production and use of carbonic acid for refrigerating and aerating. January 22  
1912 P. Everitt, London. Improvements in the manufacture of gas for incandescent lighting and apparatus therefor. January 22  
1916 C. Arkoll, Chatham. Economical preparation of brewers' distillers' and vinegar makers' worts. January 22  
1932 M. Williams, Wigan. Improvements in the purification of coal gas. January 23  
1966 T. White, Thorpe Hesley, and G. Dawson, Sheffield. Improvements in the means and apparatus for the manufacture of useful products from shale or bind or the refuse of coal or ironstone mines, and the like substances. January 23  
1985 W. Fairweather, Glasgow. Improved means or process for filtering and decolorising sugar liquors, syrups, and saccharine juices. Communicated by F. Kermann, Schoeningen, Germany. January 23  
1991 A. Gutensohn, Mile End, and A. Cox, Bristol. An improved process for the recovery of indiarubber from waste carding, cuttings, and other pieces of indiarubber cloth. January 23  
1998 J. Inray, London. A new or improved process for decarbonating carbonate of strontia. Communicated by H. Leplay, Paris. January 23  
1999 J. Inray, London. An improvement in the strontia treatment of saccharine liquors and apparatus for that purpose. Communicated by H. Leplay, Paris. January 23  
2046 B. H. Remmers, Glasgow. Improvements in apparatus for separating solid impurities from liquids. January 24  
2076 H. A. Gadsden, London. Improvements in the extraction of the metal aluminium from its ores or compounds. Communicated by E. Foote, New York, U.S.A. January 24  
2117 E. Carey, H. Gaskell, jun., and F. Hurter, Widnes. Improvements in the manufacture of hydrochloric acid and sodium carbonate from sodium chloride. January 25  
2118 E. Carey, H. Gaskell, jun., and F. Hurter, Widnes. Improvements in the treatment of sulphate of ammonia for obtaining the ammonia in the free state and utilising the sulphuric acid. January 25  
2119 A. P. Price, London. Improvements in recovering and obtaining tin from tinned metallic surfaces. January 25  
2143 G. G. Melhuish Hardingham, London. Improvements in explosive cartridges for blasting and other purposes. Communicated by T. Woolhouse, Paris. January 25  
2146 J. G. Williams, West Hampstead. Improvements in the manufacture of hydrated oxide of iron. January 25  
2157 J. H. Johnson, London. Improvements in treating ores or scoriae containing copper or nickel, and in apparatus connected therewith. Communicated by E. Hermite, Rouen. January 25  
2162 A. E. Scott, South Kensington. Improvements in treating substances and extracting metals and metalloids therefrom. January 26  
2183 R. A. Mossman, and J. Mayel Mayelston, Elloughton. The application of bicarbonate of ammonia to the leavening or expansion of dough made of wheaten flour or other farinaceous substance. January 26

- 2218 G. Baron de Overbeck, London. Improvements in the production of aluminium. Communicated to him by H. Niewerth, Hanover. January 26
- 2219 G. Baron de Overbeck, London. Improvements in explosive compounds in the nature of gunpowder. January 26
- 2220 A. Pillans Laurie, Edinburgh. Improvements in extracting lead, silver, copper, and zinc, from the bluestone ore of Anglesea and similar ores. January 26
- 2221 F. Week, Lilleshall. Improvements in machinery or apparatus for washing and scrubbing coal gas. January 26
- 2217 C. J. Lortzing, Charkow, Russia. Method to manufacture asphalt comprime or asphalt mastics from the firm residuums of the outwashing waters in the wool washings, combings, fullings, and tannings, and of all industries related to them. January 28
- 2253 H. A. Morgan and Lees Taylor, Llantrissant. Improvements in the means of or apparatus for treating tin andterne plates in the process of cleaning them. January 28
- 2263 J. D. Thomas, T. Wade Evans, and J. Gravel, Swansea. Improvements in the manufacture of tin andterne plates. January 28
- 2269 Dr. O. Hoffmann, Mainkur, Germany. The manufacture of new colouring matters. January 28
- 2279 W. T. Walker, Highgate. Improvements in apparatus for purifying coal gas. January 28
- 2286 H. L. Hake, London. Improvements in and relating to evaporating apparatus. Communicated by A. Vivien, St. Quentin, and A. D. R. Dujardin, Lille, France. January 28
- 2299 T. Griffiths, Oxtou. Improvements in the manufacture of aluminium. January 29
- 2307 L. A. White, Chorlton-on-Medlock. A process for metallising wood and other substances. January 29
- 2316 A. Wilkinson, Camberwell. Improvements in the manufacture of paper, paper-pulp, paste-board, mill-board, papier-maché, and such substances applicable for cabinet and all kinds of structural purposes. January 29
- 2323 J. Hatfield, Kew. Improvements in the manufacture of artificial stone. January 29
- 2330 H. J. Haddan, London. A new or improved process for the manufacture of alcohol. Communicated by C. Coster, Bruxelles. January 29
- 2331 G. F. Redfern, Finsbury. A new method of treating the residues from soda works. Communicated by Dr. H. Von Miller, and C. Opl, Hruschak, Austria. January 29
- 2311 A. W. L. Reddie, London. Improvements in the apparatus for and process of purifying gas. Communicated by the Smith and Sayre Manufacturing Co., New York. January 29
- 2314 J. H. Johnson, London. Improvements in apparatus for mixing and elevating sugar in course of manufacture, or for analogous purposes. Communicated by the Compagnie de Fives-Lille, Paris. January 29
- 2351 F. W. Martino, Sheffield. Improvements in the manufacture of artificial manure. January 29
- 2360 J. F. Smith, Leicester. Improvements in the manufacture of glue and size from what has been considered useless refuse. January 30
- 2368 H. Hargreaves, Congleton, W. Beckett, Oulton, and W. Cliffe, Congleton. Constructing kilns and ovens for burning limestone and bricks and other like materials. January 30
- 2372 J. K. Kaye, Moldgreen. Improvements applicable to the dyeing of black colour upon cotton and other vegetable fibres. January 30
- 2388 J. Graham Tatters, South Shields. Improvements in the mode of obtaining or recovering hydrochloric acid. January 30
- 2412 T. E. Scheele and T. Kühn, Emmerich-on-the-Rhine. Improvements in the manufacture of artificial manure. January 30
- 2415 W. T. Walker, Highgate. Improvements in apparatus employed in the purification of coal-gas. January 30
- 2418 C. D. Abel, London. Improvements in the treatment of phosphates of iron, manganese, and aluminium with the chlorides of the alkalies and alkaline earths, for obtaining alkaline phosphates and other products therefrom. Communicated by Paul Dietrich, Berlin. January 30
- 2468 H. J. Haddan, London. An improvement in the production of malt. Communicated by H. Hackmann, Mellrichstadt, Bavaria. January 31
- 2476 B. H. Remmers, Glasgow. Improvements in apparatus for cooling or heating liquids. January 31
- 2477 W. Fairweather, Glasgow. An improved filtering medium, and mode of employing the same for filtering, decolorising, and deodorising liquids and liquid solutions. Communicated by F. Kleemann, Schoeningen, Germany. January 31
- 2485 B. Midgley, Milsbridge, and W. Nunwick, Longwood. Improvements in apparatus for use in the manufacture of gas. January 30
- 2491 T. Heskin, Preston. Improvements in the mode of producing or obtaining ammoniac chloride. January 31
- 2501 W. Wyatt, Ellesmere. Improvements in the method of carrying out the process of softening and purification of water, and in apparatus for use therein. February 1
- 2539 F. Wirth, Frankfort-on-the-Main. Improvements in paints. Communicated by O. Fischer, Karlsruhe, Germany. February 1
- 2543 E. G. Brewer, London. Improvements in distilling apparatus. Communicated by D. Hainaut, Boitsford, Belgium. February 1
- 2561 C. D. Abel, London. An improvement in apparatus for drying or desiccating substances by means of heated air. Communicated by E. Langen, Cologne, Germany. February 1
- 2568 B. J. B. Mills, London. Improvements in the treatment of excremental matters, and in apparatus employed therein. Communicated by J. M. Guenantin, Paris. February 1
- 2573 A. M. Clark, London. Improvements in the process of making malleable ferro-nickel and ferro-cobalt. Communicated by the Société Anonyme dite Fonderie de Nickel et Metaux Blancs, Paris. February 1
- 2621 E. Siddons Wilson, and A. Bannen O'Connor, Camberwell. An improved method of operating upon oily and greasy rags and fibrous material, and in recovering oil and grease therefrom. February 2
- 2630 A. Gernot, and L. Riviere, Paris. An improved mode of treating certain resins for obtaining a new elastic substance. February 2
- 2638 F. Wirth, Frankfort-on-the-Main. Improvements in the method of utilising certain waste liquids. Communicated by F. Graessler, Canstatt, Germany. February 2
- 2640 A. Guattari, Paddington. Improvements in the manufacture of marble. Communicated by M. Sodorini, Florence. February 2
- 2666 J. H. Loder, Utrecht. Improvements in the manufacture of alcohol and alcoholic solutions of colouring matters, etc. February 1
- 2693 J. B. Mackey, London. The preparation of new soluble salts of cerium for medicinal purposes. Complete specification. February 1
- 2701 C. D. Abel, London. An improved process for obtaining cellulose or woody fibre from wood or other vegetable substances, and the preparation of lye therefor. Communicated by C. F. Dahl, Dantzic. Complete specification. February 1
- 2709 B. C. Sykes, M.D., and J. Briggs, Cleckheaton. Improvements in apparatus to be employed for making producer gas, heating water, and generating steam. February 5
- 2710 J. Groome, Darwen. Improvements in composition for covering steam boilers, steam pipes, or other surfaces, to prevent radiation of heat therefrom. February 5
- 2718 S. H. Emmens, and the United Patents Corporation, Limited, London. Improvements in electrolytes and in the manufacture of chemical products therefrom. February 5
- 2765 W. Brown, Branley. A new or improved means or apparatus employed in the treatment of leather during and after the "stuffing" operation. February 5
- 2787 A. Guattari, Paddington. Improvements in the manufacture of marble. Communicated by M. Sodorini, Florence. February 5
- 2796 W. H. Swim, Runcorn, and G. Pryde and J. Hedley, Liverpool. Improvements in the treatment of certain residual salts formed in the manufacture of caustic alkalies. February 6
- 2812 F. Iles, and C. Wakeman, Birmingham. A new composition or alloy entitled "pyrogen." February 6
- 2837 C. Holliday, and E. W. Hirst, Huddersfield. Improvements in dyeing wool or other similar animal fibre, and in apparatus employed therein. February 6
- 2843 J. Cripps, jun., Brixton. Improvements in the manufacture of size from wet calf, white leather, shavings, or cuttings. Complete specification. February 6
- 2847 A. Guattari, Paddington. Improvements in the manufacture of imitation marble. Communicated by M. Sodorini, Florence. February 6
- 2862 P. C. Bunn, Norwich. Improvements in the manufacture or production of pigments. February 6
- 2877 J. Johnson, Liverpool. Improvements in the manufacture of blacklead. February 7
- 2882 A. Saldé, Bonn-on-the-Rhine, and F. Schneider, Struth, Prussia. Improvements relating to the treatment and utilisation of cellulose or wood fibre. February 7
- 2896 O. Wolff, Dresden. A process of manufacturing weather-proof oil colours or paints. Communicated by A. T. Bergb, Dresden. February 7
- 2900 Bondy Anzlay, Islington. An improved process of preserving the edible parts of fish. Complete specification. February 7
- 2912 J. W. C. Holmes, Huddersfield, and B. Midgley, Milsbridge. Improvements relating to the heating of gas-retorts, spelter-pans, or the like, and apparatus therefor. February 7
- 2911 J. Knowles Kaye, Moldgreen. A new or improved method of dyeing a fast yellow colour on cotton and other vegetable fibres. February 8
- 2942 D. G. Stansby and J. Parton, Birmingham. Dividing and thereby increasing in volume and illuminating power the ordinary gas light. February 8
- 2966 C. E. Thierry, London. Improved means of treating gelatine and the like materials or substances such as imitation ivory, or what is known as porcelain and ivory, so as to prevent such materials or substances from curling when subjected to heat, and to render the same waterproof. February 8
- 2982 C. H. Roekner, Newcastle-upon-Tyne. Utilising the spent lime from bleaching powder. February 8
- 2996 L. Mond and G. Jarnay, Winnington. Improvements in and appertaining to the manufacture of sodium bicarbonate. February 9
- 3013 J. Dixon, Oughtibridge. Improvements in the manufacture of paper, and in the machinery connected therewith. Complete specification. February 9
- 3015 G. S. Hazlehurst, Rhyl. Improvements in and relating to the manufacture of salt from brine. February 9
- 3038 P. A. Maiguen, London. An improved compound for the elimination of dissolved matter from water. February 9
- 3059 H. E. Scholefield, Manchester. Improvements in the manufacture of sulphurous acid bisulphites or sulphites. February 11
- 3066 F. W. Marsh, Middlesbrough. Making gas from mineral oils. February 11
- 3073 E. Luck, London. Improvements in distilling solutions of acetic acid or vinegar. February 11

3086 M. Finch, Silvertown, and W. Willoughby, J. Willoughby, and S. Willoughby, Plymouth. Improvements in the method of and apparatus for manufacturing sulphuric acid. February 11.

3090 A. Zdzierski, Brest-Litovsk, Russia. Improvements in obtaining aluminium bronze. Communicated by J. Boguski, Warsaw. February 11.

3097 C. D. Abel, London. A manufacture of oxy-pyrazols, or substances formed by condensing hydrazines with the ethers of carbo-retonic acids. Communicated by the Farbwerke vormals Meister, Lucius, and Brünig, Höchst-am-Main, Germany. February 11.

3132 F. Firth, Dewsbury. An improved means or method of cooling the brickwork of furnaces for melting glass and other materials. Complete specification. February 12.

3166 F. Wirth, Frankfurt-on-the-Main. Improvements in the manufacture of certain sulpho-acids, and in producing colouring matter therefrom. Communicated by O. Mühlhauser, and the firm of Farbwerk, Griesheim-a-M., Dittler and Co., Griesheim, Germany. February 12.

3171 M. Ziegler, London. Improvements in the manufacture of substitutes for leather. February 12.

3236 H. Hack, Saltley, and E. Ley, Barrow-on-Trent. Apparatus for receiving and conveying away coke drawn from gas retorts or coke ovens, and for delivering the same into wagons, barges, or elsewhere. February 12.

3240 J. Lewthwaite, Halifax. Improvements in metals and alloys or mixtures of the same. February 13.

3244 W. R. Lake, London. Improvements in the manufacture of sugar, and in apparatus therefor. Communicated by K. Trobach, Berlin. Complete specification. February 13.

3249 W. R. Lake, London. Improvements in the preparation of selenium for, and the manufacture of, selenium cells for electrical purposes, and apparatus therefor. Communicated by C. E. Fritts and D. H. Hopkinson, New York. Complete specification. February 13.

3255 C. J. Flather, Southport. The removal of the incrustation in steam boilers, pipes, cisterns, and other vessels. February 14.

3309 W. A. Barlow, London. A new and improved system of apparatus for evaporation and distillation, and for the practical application of the same. Communicated by P. Calliburees, Paris. Complete specification. February 14.

3323 F. Wirth, Frankfurt-on-the-Main. Improvements in the method of and apparatus for treating acid-sulphate of soda or bisulphate of soda for industrial purposes. Communicated by H. Herberts, Barmen, Germany. February 14.

3355 C. D. Abel, London. An improvement in furnaces for burning small, moist, or liquid fuel. Communicated by G. A. Godillot, Paris. Complete specification. February 15.

3363 J. Elliott and F. J. Parsons, Hastings. Improvements in the manufacture of artificial stone, paving slabs, and blocks. February 15.

3365 A. Thomas, West Cowes. Testing gas for impurities. February 15.

3370 D. H. Dade, Oglander Road, Surrey. Improvements in non-conducting and fire-proof compositions and articles. February 15.

3375 J. Salamon, Wennington. An improved process of tanning hides or skins. Communicated by L. Vergez, Tarbes, France. February 15.

3378 W. Guest, New Cross. Improvements in the treatment of leather. February 15.

3382 T. Carlile and J. Park, Glasgow. Improvements in the manufacture of bichromate of soda. February 16.

3405 A. Wright, London. The production, distribution, and administration of spray or vapour, called the "Atmonemeter." February 16.

3417 J. Nuttall, Rochdale, F. Nuttall, Oldham, and J. Rouse, Oldham. Method for purifying noxious or gaseous vapours arising from heated liquids, oily or other matters, and in apparatus used therein. Complete specification. February 16.

3433 J. H. Johnson, London. Improvements in treating saccharine solutions for the purpose of extracting the sugar therefrom. Communicated by V. Four, Paris. February 16.

3434 L. A. Groth, London. Improvements in the manufacture of night and other illuminating lights. Communicated by F. E. Berta, Fulda, Germany. Complete specification. February 16.

3435 B. Tower, Westminster. An improved method and apparatus for condensing steam or vapour. February 16.

3441 C. Hunt, Birmingham. Improvements in the arrangement of the air and waste-gas passages in connection with regenerator furnaces. February 16.

3452 H. H. Lake, London. Improvements in apparatus for distilling liquids for purifying gas and for similar purposes. Communicated by P. A. Mallet and T. A. Pagniez, Paris. February 16.

3465 J. Peddar, Appleton-in-Widnes. Improvements in abstracting valuable properties from solutions, and in apparatus therefor. February 18.

3471 C. J. Ellis, Glasgow. Improvements in obtaining sulphate of soda, and in apparatus therefor. February 18.

3483 W. Martyn, Wadebridge. Dissolving leather for use as a manure. February 18.

3498 H. Barclay and E. Simpson, Harrington. Improvements in the collection and treatment of fine-dust. February 18.

3520 E. W. Scofield, Brixton. Compound for sweetening or restoring sour liquids, and for other purposes. February 18.

3526 J. G. Willans, West Hampstead. Improvements in carbonising coal. February 18.

3528 H. Townsend, Bradford. Improvements in the process of and apparatus for the manufacture of gas. February 18.

### COUNCIL.

*President:* Walter Weldon, F.R.S.

*Vice-Presidents who have filled the Office of President:*  
Sir Frederick Abel, C.B., D.C.L., F.R.S.  
Professor H. E. Roscoe, Ph.D., LL.D., F.R.S.

*Vice-Presidents:*

I. Lowthian Bell, F.R.S.	David Howard.
George E. Davis.	E. K. Muspratt.
J. H. Gilbert, D.C.L., F.R.S.	H. Lee Pattinson.
F. H. Gossage.	W. H. Perkin, Ph.D., F.R.S.
D. B. Hewitt, M.D.	Prof. James Dewar, F.R.S.

*Ordinary Members of the Council:*

Eustace Carey.	John Pattinson.
Alexander M. Chance.	B. S. Proctor.
Prof. Chas. Graham, D.Sc.	R. Angus Smith, Ph.D.,
Peter Griess, Ph.D., F.R.S.	F.R.S.
James Maclear.	John Spiller.
R. Messel, Ph.D.	John Williams.
	P. J. Worsley.

With the Chairmen and Secretaries of Local Sections.

*Honorary Treasurer:*

E. Rider Cook, East London Soapworks, Bow, E.

*Honorary Foreign Secretary:*

Ludwig Mond, Winnington Hall, Northwich.

*General Secretary:*

Charles G. Cresswell, Palace Chambers, 9, Bridge Street,  
Westminster.

C. C. Hutchinson.	Sydney Young, D.Sc.

*Japanese Correspondent:* T. Takamatsu.

### NOTICES.

#### ANNUAL GENERAL MEETING.

The next Annual General Meeting of the Members of the Society of Chemical Industry will be held at Newcastle-on-Tyne, in July. Its exact date is not yet fixed, but will be announced in due course.

The morning of the first day of the meeting will be devoted to the transaction of the ordinary business of the Society and an address by the President, and the afternoon to a visit to a chemical work. In the evening those of the members attending the meeting who wish to do so will dine together. Members may obtain dinner tickets for their friends.

At the last Council meeting it was resolved, "That the Council desires to record its entire approval of the decision of the Newcastle Section that at the annual dinner in July there shall be two classes of dinner ticket, one for dinner without wine and one for dinner with wine."

It is proposed that the morning of the second day of the meeting shall be devoted to the reading and discussion of papers on the more important of the recently-proposed methods for utilising the condensable products obtainable from coal used in the manufacture of coke, coal used in blast furnaces, and coal used as fuel. Members who may desire to read papers on any branch of this subject are invited to communicate with the General Secretary.

Papers by Mr. W. S. SUTHERLAND and Mr. GEORGE BEILBY are already promised, and others are being arranged for. By the kind courtesy of Messrs. BAIRD AND COMPANY, those members who choose to visit Gartsherrie will be permitted to see the process at work there. Mr. BEILBY has kindly arranged that those who wish to do so may see the YOUNG and BEILBY process in operation at two works near Edinburgh; and it is expected that opportunities will also be afforded of seeing in operation both the JAMESON process and the SIMON-CARVES process. The afternoon of the second day of the meeting will probably be devoted to visits to various works in the neighbourhood of Newcastle, and the members will probably be invited to a conversazione in the evening.

Full particulars of the arrangements for the meeting will be given in the June number of the Journal.

Numerous inquiries have been made for sets of the Journal for 1882. Some of the numbers for that year are out of print. Members who have not the volume for 1882, and wish to obtain it, are invited to signify that wish to the Secretary as early as possible. If a sufficient number of applications for that volume are received, the missing numbers of it will be reprinted.

The Proceedings of the First General Meeting (1881) of the Society of Chemical Industry have been reprinted in such size and style as to permit of their being bound up with the Journal. Copies of the reprinted Proceedings will be forwarded by the Publishers on receipt by them of twelve penny stamps for each copy required.

In this number of the Journal is inserted, as the first of a series, a list of changes which have taken place during the month in the residence and in their relation to the Society of some of the members, for the information of the Society's officers and of whomsoever else it may concern. The General Secretary trusts that members will second his efforts to make this list a complete and accurate record by notifying to him their changes of address as promptly as possible.

Authors of papers printed in the Journal are hereby notified of the fact that, in accordance with Bye-law 36, they are entitled to receive not more than 50 gratuitous copies of their papers. Authors should state on their manuscripts their desire to have free copies, adding the number wished for. Unless the contrary be specially desired, this being stated on the manuscript, the reprints of an author's paper will not include the report of any discussion that may have arisen after the reading of the paper.

#### LIST OF MEMBERS ELECTED MARCH 21st, 1884.

J. H. Bald, Braddock, Pennsylvania, U.S.A., chemist, steel-works.  
 Jesse P. Battershall, Ph.D., 402, Washington Street, New York, U.S.A., chemist.  
 William Beardmore, Parkhead Forge, Glasgow, steel manufacturer.  
 R. W. Peregrine Birch, M.I.C.E., 2, Westminster Chambers, Victoria Street, London, S.W.  
 W. B. Cogswell, Syracuse, New York, U.S.A., chemical engineer.  
 Azariah Griffiths, Clyde Cottage, Falkirk, N.B., fireclay manufacturer.  
 Alf. Hunzinger, care of E. Potter and Company, Dinting Vale, Glossop, near Manchester.  
 F. J. Lloyd, 4, Lombard Court, Gracechurch Street, E.C., analyst.  
 Otto Luthy, 225, Church Street, Philadelphia, U.S.A.  
 Donald McDonald, Invernevis, Port William, N.B., distiller.  
 John McGowan, Ash House, Talk-o'-th'-Hill, near Stoke-on-Trent, colliery manager.  
 A. Russell Miller, The Cairns, Cambuslang, near Glasgow, chemist.  
 T. Paterson Miller, The Cairns, Cambuslang, near Glasgow, Turkey-red dyer and calico printer.  
 John Murphy, 11, Wellesley Terrace, Prince's Park, Liverpool, chemical manufacturer.  
 K. Oehler, Offenbach-am-Main, Germany, anilin dye manufacturer.  
 Andrew Pears, Lanadron Soapworks, Isleworth, Middlesex, wholesale perfumer.  
 F. W. Richardson, 40, Church Street, Manningham, Bradford, analyst.  
 J. W. Roxburgh, Levenbank Works, Jamestown, Dumbartonshire, manager.  
 Ernest Smith, 114, West Street, Glasgow, manufacturing chemist.  
 Adolph Sommer, 529, Market Street, San Francisco, U.S.A., pharmacist.  
 Charles Stephens, F.L.S., Avenue House, Finchley, ink manufacturer.  
 David Stewart, Woodside, Wemyss Bay, Renfrewshire, N.B., technical chemist.  
 Richard Tangye, Gilbertstowe Hall, Bickershill, near Birmingham.  
 Gottfried Delitsch, 30, Raeburn Place, Edinburgh, chemist and manager.  
 Robert Hamilton, jun., Westthorn, Tolleross, Glasgow, analyst.  
 Howard P. Ryland, The Cedars, Gravely Hill, Birmingham.  
 Howard Charles Ward, Sussex Villa, Putney Park Avenue, London, S.W., barrister-at-law, deputy-chairman Gas Light and Coke Company Limited.  
 George B. Anderson, Palm Cottage, Runcorn, Cheshire, manager alkali works.  
 James Angus, Lugar, Ayrshire, N.B.  
 John Currie, 38, Bridge Street, Alexandria, Dumbartonshire, chemist.  
 John Dyson, 231, York Street, Cheetham, Manchester.  
 Thomas L. Eastlake, 23, Great George Street, Westminster, London, S.W.  
 G. H. Irvine, 2, Salisbury Quadrant, Strathbungo, Glasgow, chemist.  
 William Kennedy, 28, Royal Exchange Square, Glasgow, managing director of Broxburn Oil Company Limited.  
 James Mavor, 131, St. Vincent Street, Glasgow, drysalter.  
 James Muter, 2, West View Gardens, Dennistoun, Glasgow, assistant professor of "technical chemistry" ("Young" chair), Anderson's College.

J. Barton Scammell, 13, Lordship Park, Stoke Newington, London, N.  
 G. R. Tweedie, 13, Chantry Road, Brixton, London, S.W., analyst.  
 J. H. Wainwright, 402, Washington Street, New York, U.S.A.

#### CHANGE OF ADDRESS REQUIRED.

Irwin, J. T. (late of 261, Blackburn Road, Acerington).

#### RESIGNATIONS.

R. V. Bethel, R. M. Morris, H. Salvin Pattinson, Alfred Payne, W. G. Whittam, H. J. Smith.

#### NAMES OF NEW MEMBERS ACCIDENTALLY OMITTED IN SUPPLEMENTARY LIST, FEBRUARY.

Cresswell, C. N., 1, Hare Court, Temple, London, E.C.  
 West, John, Barfield House, Didsbury, near Manchester.

## London Section.

Chairman: David Howard.

### Committee:

Sir F. A. Abel.	R. Messel.
E. Rider Cook.	B. E. R. Newlands.
W. Crowder.	Thos. Royle.
Dr. E. Frankland.	John Spiller.
Prof. Charles Graham.	G. C. Trewby.
F. Maxwell Lyte.	C. Umney.
Geo. Matthey.	J. Williams.

Local Sec.: Thos. Tyrer, Battersea, S.W.

The meetings of this Section are held on the first Monday in each month.

The following altered arrangements for papers for the remainder of the Session are notified:—

On April 7th, Election of Local Committee. Dr. Armstrong, "Preliminary Note on Certain By-products of the Pintsch Oil Gas Manufacture in Relation to the Question as to the Conditions under which Benzenes are Formed." Messrs. Giles and Shearer, "On the Estimation of Sulphurous Acid in its Compounds." Mr. W. L. Carpenter, "Further Note on the Solidification of Liquid Oils."

On May 5th, Dr. Percy Frankland, "On the Composition and Illuminating Power of Coal Gas." Mr. W. J. Diddin, "On the Estimation of the Illuminating Power of Gas Burners, especially those of large size."

On June 3rd, Mr. W. S. Squire, "On the Processes Concerned in the Conversion of Starch into Alcohol, and their relation to Brewing and Distilling," illustrated.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE,  
Monday, March 3rd, 1884.

MR. DAVID HOWARD IN THE CHAIR.

## ON THE MANUFACTURE OF CUPRAMMONIUM AND ZINCAMMONIUM COMPOUNDS AND THEIR TECHNICAL ADAPTATION.

BY C. R. ALDER WRIGHT, D.S.C., F.R.S.

It has long been known that when an aqueous solution of ammonia is added to one of certain metallic salts, a precipitate is at first formed which redissolves on further addition of ammonia, forming a fluid from which in many cases definite crystallised compounds can be isolated by evaporation, or by treatment with alcohol or a large excess of concentrated ammonia solution, etc., so as to cause the compound to separate through being comparatively insoluble in the modified menstruum. These compounds usually contain the elements of the metallic salt originally used together with those of ammonia, and in some cases water (of crystallisation or constitutional). Copper and zinc belong to the class of metals the salts of which behave in this way. Various kinds of ammonia compounds of different salts of these two metals have been described by different observers, the best defined of which in the cupric series belong to the tetrammonio class  $\text{CuX}_2 \cdot 4\text{NH}_3$ , or  $[\text{Cu} \cdot 4\text{NH}_3] \text{X}_2$ —as, for example, cuprotetrammonium sulphate  $[\text{Cu} \cdot 4\text{NH}_3] \text{SO}_4$ ,  $\text{H}_2\text{O}$ , which is readily obtained in crystals by adding to a concentrated copper sulphate solution ammonia in large excess, or ammonia in less excess and alcohol. The similarly-constituted cuprotetrammonium bromate, nitrate, hyposulphate, and various other salts are similarly obtainable. Under the influence of heat these compounds lose ammonia, forming analogous but less ammoniated compounds. Thus cuprotetrammonium sulphate at near  $150^\circ \text{C}$ . loses  $2\text{NH}_3$ , and at about  $205^\circ \text{C}$ . loses another  $\text{NH}_3$ , and finally at about

$260^\circ \text{C}$ . loses the last  $\text{NH}_3$  present, thus forming in succession the series—

Metals the salts of which form with ammonia compounds of this kind are usually capable of giving rise to another class of ammonio-metallic derivatives by dissolving their oxides or hydroxides in excess of ammonia solution. In some cases, *e.g.*, with copper, these fluids are readily formed by agitating scraps of the metal with air and ammonia solution, the metal spontaneously oxidising under these conditions with considerable rapidity. In other cases, *e.g.*, zinc, the metal when in contact simultaneously with air and ammonia solution does not oxidise rapidly, but the action can be brought about more readily by conjoining to the chemical agencies at work the galvanic effect of the admixture of another metal in contact with the one to be dissolved. Thus a mixture of zinc and iron cuttings is far more effective in producing solution of the former metal than the cuttings of zinc alone, although the iron remains practically unaffected. It is remarkable that brass dissolves in ammonia as a whole, both zinc and copper going into solution under the influence of aerial oxidation. It is usual to assume that the compounds formed by the union of ammonia with metallic salts, oxides, or hydroxides, are the corresponding salts, oxides, or hydroxides of compound metallo-ammoniums. From this point of view cuprotetrammonium sulphate may be regarded as—

or ammonium sulphate, in which  $\text{H}_2$  are replaced by the diad group—

In the same way the solution of copper oxide in excess of ammonia may be regarded as—

Similar remarks apply to the zincammonium derivatives. In the case of cupro- and zinc- ammonium compounds, the stability of the substances under ordinary conditions is not great. Even at ordinary temperatures there is usually a more or less marked tendency to decompose evolving ammonia; thus cuprammonium hydroxide solution is decomposed by addition of a large bulk of alcohol, a blue precipitate being thrown down consisting essentially of hydrated copper oxide (usually also containing a little carbonic acid and ammonia associated therewith); and on long standing (some weeks or months) concentrated solutions deposit a black substance lining the containing vessel, essentially consisting of anhydrous copper oxide. Similarly, cuprotetrammonium sulphate crystals are broken up by contact with a large bulk of cold water into free ammonia, ammonium sulphate, and a blue precipitate of variable composition, but essentially consisting of a "basic" sulphate,  $\text{CuSO}_4 + \text{NCuO}_2 \cdot \text{H}_2\text{O}$ , also retaining a little ammonia. In presence of excess of ammonia, cuprotetrammonium sulphate wholly dissolves to a blue liquid, which, if strongly ammoniacal, may be evaporated down on the water-bath without any considerable amount of change, forming a thick residue mostly soluble in a small bulk of water. On continued boiling of a less ammoniacal solution, however, black cupric oxide is formed, with more or less basic sulphate. Some interesting illustrations of the influence of mass and temperature on decomposition are afforded by these reactions; into these points, however, it would be out

of place now to enter. It is noteworthy that zinc ammonium hydroxide solutions deposit, on long standing, crystals essentially consisting of zinc hydroxide,  $\text{ZnO}$ ,  $\text{H}_2\text{O}$ . If carbonic acid be excluded, the crystals are often perfectly clear and transparent, but are more or less white and opaque, and consist of a "basic" carbonate,  $\text{ZnCO}_3 \cdot \text{N}_2\text{H}_4 \cdot \text{H}_2\text{O}$ , if the solution contains ammonium carbonate.

According to Wetzlar cuprammonium hydroxide solution containing sal-ammoniac or certain other salts attacks metallic iron, causing copper to be deposited in the metallic form and oxide of iron to be produced. Pure cuprammonium hydroxide containing a large excess of ammonia, however, is found in actual practice on the large manufacturing scale to cause no noticeable corrosion of either wrought or cast iron, or of steel, so that receptacles for the fluid,

considerable scale to practical manufactures, although various modes of employment of them have been from time to time proposed and even patented. For a long time these fluids have been used in small quantities as tests of the character of certain organised fibres, *e.g.*, silk, cotton, linen, etc., on account of their power of dissolving, or at any rate of pectising, gelatinising, and disintegrating\* these fibres. Recently C. F. Claus has patented the production of a kind of silicate of zinc by the addition of silicate of soda to ammoniacal zinc solution; whilst the zinc hydroxide left on goods treated with zincammonium hydroxide solution and exposed to the air is capable of acting as a mordant, although it does not appear to have been largely employed in that direction as yet. Of late years, however, an attempt has been made to utilise on a manufacturing scale the remarkable power

FIG. 1.

and also machinery, can safely be constructed of iron or steel without fear of injury, even when kept in prolonged contact with the solution. In this respect iron differs remarkably from zinc. Both metals readily displace copper from solution in ordinary salts, *e.g.*, copper sulphate; but with regard to an ammoniacal solution their behaviour is not the same, iron having no action, but zinc precipitating copper as readily as from an ordinary salt, and forming in so doing zincammonium hydroxide solution—in fact, this reaction forms a most convenient way of preparing that fluid on the large scale.

Owing probably to the want of permanence of cupro- and zinc-ammonium compounds, and the cost of the large quantity of ammonia solutions requisite to form and preserve them, these substances do not appear as yet to have been applied on any

possessed by cuprammonium solutions of pectising cellulose and similar substances, in such a fashion as to produce a partial alteration somewhat analogous to that brought about by dipping paper into sulphuric acid so as to "parchmentise" it. After much laborious experimentation, the processes originally patented by the late Dr. John Scoffern have been improved and reduced to a regular manufacture by the Patent Waterproof Paper and Canvas Company, of the Canal Works, Willesden Junction, whose specialties are known as "Willessden" fabrics, amongst which may be particularly noticed a waterproof paper for lining damp walls, a variety of thicker cards for roofing and

\* According to Erdmann (*J. Prakt. Chem.* lxxvi., 385) cellulose is not truly dissolved by ammoniacal copper solutions, but is only disseminated through the fluid in a gelatinised condition.

other analogous purposes, and canvas and ropes, etc., prepared so as to be rotproof.

The process by which these fabrics are manufactured may be described as essentially consisting of the preparation of a concentrated solution of cuprammonium hydroxide, and the passing of the goods to be treated through a bath of this material at just such a rate as will permit of the pectising and gelatinising of the exterior of the fibres composing the paper or canvas, etc., without wholly disintegrating the mass; so that the material on emerging from the bath retains coherence sufficient to enable it to be passed over and under the usual drums, etc., of a paper mill, and so to be dried in the ordinary way. This drying converts the film of pectised cellulose coating each filament and fibre into an insoluble solid varnish which cements the whole together, forming a material entirely *sui generis*. In order to build up thick cards two or more reels of paper are employed, passed simultaneously through the bath, and then pressed together and dried as a whole, two thicknesses thus treated forming two-ply card. The best kinds of thick cards are made by passing two rolls of two-ply simultaneously through the bath a second time and pressing them together and drying, thus giving rise to four-ply card, the thickness mostly adopted for roofing. By repeating this process with two batches of four-ply, eight-ply is obtained; and similarly to any required degree of thickness necessary for special purposes.

ever, does not pectise paper sufficiently to give good results. In order to pectise paper, etc., thoroughly when the materials are passed through the baths at a convenient manufacturing speed, it is essential to use a liquid containing 100 to 150lb. of ammonia per 100 gallons \* (about as much ammonia as is present in solution of ammonia, specific gravity '940 to '960). Such a fluid, when nearly saturated with copper present as pure cuprammonium hydroxide, will contain 20lb. to 25lb. copper (reckoned as metal) per 100 gallons. Considerably larger amounts of copper, however, may be taken into solution in the form of cuprammonium salts, or when certain forms of organic matter are also present in the liquor. According to the textbooks, ammoniacal solutions of cuprammonium salts dissolve cellulose, but such fluids are found to be unsuitable for the manufacture of Willesden goods for a variety of reasons. In the first place, for a given quantity of copper in solution an ammoniacal solution of cuprammonium hydroxide appears to possess a considerably higher pectising power than a similar solution of a cuprammonium salt; next, when a cuprammonium salt, *e.g.*, the sulphate, is used there is not only a tendency to form a little copper sulphate, which can be washed out of the finished fabric by water (thus rendering the material unsuitable for many purposes, *e.g.*, cattle drinking-troughs, portable sheep-pens, etc.), but further, much ammonium sulphate is formed in the body of the fabric, thus giving rise to a double dis-

FIG. 2.

A noteworthy point in connection with these processes is that, when certain precautions are taken, the copper present in the ammoniacal fluid imbibed by the material passed through the bath is wholly converted during drying into a compound with the pectised cellulose of an agreeable green tint, and is not deposited as black oxide of copper, as it would be on evaporation of the solution without cellulose in a porcelain dish, etc. It is largely the presence of copper in this form that renders Willesden fabrics so free from growths of mould, mildew, rot, and fungoid vegetation generally, and from the attacks of insects. The compound is so stable as to be wholly unaffected by water, when once dry. Of course, mineral acids dissolve out copper to some extent, but this is not the case with ordinary water, apparently not even with London rain. Instead of cuprammonium hydroxide alone, in certain cases a mixture of cuprammonium and zincammonium hydroxides may be used. The pectised cellulose then contains both zinc and copper, indicating apparently that a zinc cellulose compound has also been formed. Zincammonium hydroxide alone, how-

ever, does not pectise paper sufficiently to give good results. In order to pectise paper, etc., thoroughly when the materials are passed through the baths at a convenient manufacturing speed, it is essential to use a liquid containing 100 to 150lb. of ammonia per 100 gallons \* (about as much ammonia as is present in solution of ammonia, specific gravity '940 to '960). Such a fluid, when nearly saturated with copper present as pure cuprammonium hydroxide, will contain 20lb. to 25lb. copper (reckoned as metal) per 100 gallons. Considerably larger amounts of copper, however, may be taken into solution in the form of cuprammonium salts, or when certain forms of organic matter are also present in the liquor. According to the textbooks, ammoniacal solutions of cuprammonium salts dissolve cellulose, but such fluids are found to be unsuitable for the manufacture of Willesden goods for a variety of reasons. In the first place, for a given quantity of copper in solution an ammoniacal solution of cuprammonium hydroxide appears to possess a considerably higher pectising power than a similar solution of a cuprammonium salt; next, when a cuprammonium salt, *e.g.*, the sulphate, is used there is not only a tendency to form a little copper sulphate, which can be washed out of the finished fabric by water (thus rendering the material unsuitable for many purposes, *e.g.*, cattle drinking-troughs, portable sheep-pens, etc.), but further, much ammonium sulphate is formed in the body of the fabric, thus giving rise to a double dis-

\* 1 gramme per litre = 1lb. per 100 gallons, a relationship convenient to remember, when laboratory tests are made using the metrical system, whilst British weights and measures are used in the actual works.

vegetable fibres by its solvent action thereon. For the economical production of the fluid at the rate of several tons at an operation, apparatus and methods had to be devised, more especially with the twofold object in view of causing the solution of copper in as short a period as possible, and of preventing ammonia being lost in large quantities during the operation. Whilst pursuing the investigations necessary for the attainment of this object, several points of interest were observed which may be here fitly recorded.

*As to the relationship between the ammoniacal strength of aqueous solution of ammonia and its specific gravity at some assigned constant temperature.* A number of careful observations were made (in conjunction with Mr. C. Thompson) with different aqueous solutions of ammonia, the relative weights of equal bulks of the solutions and of distilled water at 18.5° C. being determined, and also the percentage of ammonia present. From the results obtained the figures given in the second column of the following table were deduced by interpolation. The third and fourth columns show respectively the percentages of ammonia found by Carins and by Otto in liquids of the gravities cited, the temperature of comparison with water being 14° C. and 16° C. respectively. The most probable mean results for the temperature 16.2° C., taking into consideration all the observations, are given in the fifth column, whilst the sixth column represents the number of grammes per litre (or pounds per 100 gallons) of ammonia present thence deduced, and the seventh the difference in number of pounds per gallon per .001 difference in specific gravity.

Sp. Gr.	Per cent. of Ammonia at 18.5° Alder Wright and Thompson.	Per cent. of Ammonia at 14° Carins.	Per cent. of Ammonia at 16° Otto.	Most probable Mean at 16.2°	Grammes per litre (or lbs. per 100 gallons) at 16.2°	Difference per .001 sp. gr.
1.000	0	0	—	0	0	—
.995	1.16	1.209	—	1.17	11.64	2.33
.990	2.32	2.375	—	2.34	23.17	2.31
.985	3.48	3.525	—	3.52	34.67	2.30
.980	4.74	4.725	—	4.73	46.35	2.34
.975	6.00	5.975	5.850	5.97	58.21	2.37
.970	7.27	7.225	7.175	7.23	70.13	2.38
.965	8.54	8.514	8.500	8.52	82.22	2.42
.960	9.81	9.825	9.800	9.83	94.37	2.43
.955	11.19	11.171	11.125	11.16	106.58	2.44
.950	12.56	12.513	12.416	12.53	119.01	2.49
.945	13.91	13.971	—	13.96	131.93	2.58
.940	15.17	15.100	—	15.41	145.14	2.64
.935	17.01	16.900	—	16.96	158.58	2.68
.930	18.54	18.467	—	18.50	172.05	2.69
.925	20.08	20.033	—	20.06	185.55	2.70

The following table indicates the results of some experiments on the alteration in specific gravity produced by temperature variation with liquids of various strength:—

Sp. gr. at 18.5°	Variation in sp. gr. per 1° alteration in temperature.
.925	.0005
.940	.0003
.960	.0001
.980	.00005

Hence a liquid of specific gravity .925 at the temperature 16° would at 18° become lighter by an amount substantially equal to  $(18-16) \times .0005 = .001$ , *i.e.*, its specific gravity at 18° would be .925 - .001 = .924. Similarly at 20° its specific gravity would be .925  $(20-16) \times .0005 = .923$ . Again, a liquid of specific gravity .940 at 21° would have at 16° the specific gravity .940  $+(21-16) \times .0003 = .9415$ , and so on. These figures do not pretend to extremely minute accuracy, but they are quite accurate enough to show that a difference of two or three degrees in the tem-

perature at which the specific gravity is tested will make a very material difference in the amount of ammonia present deduced from the specific gravity determination, the effect being more marked the stronger the solution. For instance, a fluid testing .925 at 20° 2, instead of containing 185.55 lb. of ammonia per 100 gallons (grammes per litre), as it should do were its specific gravity .925 at 16° 2, will only contain as much ammonia as solution of specific gravity .925  $+(20-16) \times .0005 = .927$ ; that is, will only contain  $185.55 - 2 \times 2.70 = 180.15$  lb. per 100 gallons, or almost exactly 3 per cent. less ammonia. Inasmuch as temperature observations are often altogether omitted in testing goods by specific gravity, whilst thermometers, if used, are apt to be erroneous by two or three degrees, especially those of the cheaper kinds—and further, inasmuch as hydrometers are rarely exact within  $\pm .001$ , and are often erroneous to a much greater extent—it is evident that the above table of ammoniacal strengths is far more sharply exact than the exigencies of commerce require; and further, that if estimations of strength of higher accuracy than say 5 per cent. be desired, the indications of the hydrometer must not be relied upon, but a proper quantitative analysis must be made. *Mutatis mutandis*, the same remarks apply to the testing of most other fluids by means of the hydrometer. In connection with this subject it is of interest to notice that the specific gravity of a pure cuprammonium hydroxide solution is found experimentally to be always higher than that of an aqueous solution of ammonia alone, containing the same amount of ammonia and at the same temperature, by an amount equal to  $n \times .00159$  where  $n$  is the number of pounds of copper (as metal) present per 100 gallons (grammes per litre). Several comparisons with liquors containing widely-different amounts of copper and of ammonia led to numbers differing from the mean constant .00159 by quantities in no case exceeding the limits of observational error. Thus, for instance, a solution of cuprammonium hydroxide containing at 16.2° 10 lb. of copper and 119.04 lb. of ammonia per 100 gallons has the specific gravity at 16.2° of  $.950 + 10 \times .00159 = .9659$ .

*As to the quantity of ammonia capable of being taken up by air in contact with aqueous ammonia solutions of various strengths at common temperatures.*—At the ordinary temperature and pressure (say 15° C. and 760 mm.) 100 gallons of air contain about 253 lb. of oxygen, capable if fully absorbed, of converting rather more than 1 lb. of metallic copper into cupric oxide. Hence, in order to dissolve in 100 gallons of ammoniacal solution 253 lb. of copper, a volume of air will be requisite equal to about 25 times the bulk of the solution (2,500 gallons) if all the oxygen be removed, and proportionately more if only a portion of the oxygen be absorbed. It is obvious that the unused nitrogen or "spent air" will carry away a considerable amount of ammonia, and presumably more the higher the temperature and the stronger the ammoniacal fluid used. In actual practice it is found that the ammonia thus carried away is so large a fraction of that originally present in the ammoniacal solution as to make it indispensable to recover it. In order to determine with a fair approach to accuracy the actual amount of ammonia thus carried away in different cases, several series of observations were made with air saturated with moisture and ammonia vapour by slowly bubbling it through a bulk of ammonia solution large enough to undergo no material diminution in strength during the experiment. The ammonia was determined by passing the air through an acid solution of known strength, and the quantity of air employed by simply collecting and measuring it. The following table gives the mean results of a number

of concordant observations thus made at 16° C. and at 29° C. :—

Pounds Ammonia per 100 gallons in the fluid employed to saturate the air.	Pounds Ammonia removed per 100 gallons of effluent air measured at 0° and 760mm.		
	At 16° C.	At 29° C.	Average Difference per 1° C.
188	249	546	023
164	176	355	011
141	130	252	0094
121	096	182	0066
92	063	118	0042
62	038	070	0025
33	0185	032	00103

The curves drawn (Fig. 1) represent these values. It is hence evident that to dissolve 25lb. of copper (requiring, as above shown, some 2,500 gallons of air) will mean the carrying away of from 5lb. to 20lb. of ammonia at spring and summer temperatures from liquid originally containing 150lb. to 160lb. per 100 gallons, even if all the oxygen be utilised; whilst if only one-fourth of the oxygen be fixed by the copper, four times as much will be removed. Practical experience in the works is in harmony with these deductions, a very considerable fraction of the ammonia originally present being removed by the air employed to oxidise and dissolve the copper. Accordingly the apparatus employed at Willesden for the manufacture of cuprammonium hydroxide solution (conveniently termed "Blue liquor") is so designed as to meet this difficulty, the ammonia being regained in accordance with Alder Wright's patent in the form of a comparatively weak cuprammonium hydroxide solution.

*As to the rate of solution of metallic copper when agitated with air and aqueous solution of ammonia.*—A number of laboratory experiments were made, using a glass cylinder filled with crumpled-up fragments of sheet copper over which ammonia solution was poured. A stream of air was then made to bubble through the whole, whereby the copper was rapidly oxidised and dissolved. Samples being drawn from time to time and analysed, data were obtained for drawing curves, the times since commencing being abscissæ and the amount of copper taken into solution ordinates. Fig. 2 illustrates such a curve obtained with a cylinder containing a column of copper fragments 9 inches in height, and solution of ammonia of about 155lb. per 100 gallons. The air stream was such as to give about 40 times the bulk of fluid used per hour (measured at the ordinary temperature and pressure).

Time since commencement. Minutes.	Copper in pounds per 100 gallons of fluid.	Gain per hour.
5	1.05	—
60	7.50	7.04
150	12.15	3.30
200	15.00	3.06
215	17.20	3.13
305	19.50	2.30
365	21.15	1.95
485	25.10	1.82

It is here obvious, first, that the rate of solution gradually slackened as the liquid became richer in copper; and secondly, that even at the period when the rate of solution was most rapid, only about a sixth of the oxygen in the air used was fixed by the copper; for an air stream of 40 volumes per hour would suffice to dissolve slightly more than 40lb. of copper per hour per 100 gallons, whilst 7.04 was the maximum rate actually observed. Precisely analogous results were obtained in numerous other experiments with copper columns of very varying magnitudes; *ceteris paribus* increasing the length of column increased the rate of

solution. But even with a column 30ft. long the majority of the oxygen of the air escaped unabsorbed except when this rate of passage was so slow that it would necessarily introduce practical inconveniences through delay in manufacture if such a method were adopted. Based upon the knowledge derived from the foregoing and other analogous laboratory experiments, a system of manufacture of blue liquor was finally devised, which, after trying on a small manufacturing scale, and undergoing some slight modifications in consequence, was finally adopted, the result of which is that cuprammonium hydroxide solution can be manufactured without any practically appreciable loss of ammonia of any acquired richness in either copper or ammonia compatible with the degrees of solubility of those substances. On account of their spontaneous decomposition with separation of black oxide of copper on long keeping, solutions of cuprammonium hydroxide are not adapted for export or long storage, when of considerable richness of copper—at least they necessarily deteriorate as regards the amount of copper in solution, although not appreciably in any other respect. When, however, the amount of copper does not exceed some 12lb. or 15lb. per 100 gallons, little or no depreciation takes place even on keeping for a twelvemonth, whilst weaker solutions may be kept unchanged for an indefinitely long period. Such solutions appear amongst other purposes to be well adapted for the treatment of sleepers and timber generally for the purpose of preservation against decay and insect life. Zincammonium-hydroxide solutions also appear to possess properties rendering them susceptible of various useful applications. They are readily obtainable by means of the methods used for the preparation of cuprammonium hydroxide. Copper scrap, or preferably refuse brass, is dissolved up in ammonia, and the mixed copper and zinc solution obtained digested with old zinc (worn-out roofings, gutters, etc.), so as to throw down the copper as precipitated copper, which may be dissolved up over again if required, and form a solution containing zinc only. Besides the interest to chemists afforded by the peculiar properties of these ammonio-metallic solutions, and to chemical manufacturers by the introduction of a method of manufacturing them in quantity without considerable expense, there is another point connected with the matter which may be of some interest to the Society of Chemical Industry, viz., the various directions in which the Willesden fabrics, and more especially the card, can be turned to account in a factory. For the construction of light yet extremely durable roofs and sheds either permanent or portable; for temporary offices and workmen's tents used during the construction of large engineering works, *e.g.*, bridges, railways, etc.; for shelters to keep rain off hay and corn ricks, barns, and numerous other farmyard purposes; for drinking troughs, water-storage tanks, sheep-pens, portable photographer's dark rooms, sentry boxes, bathing boxes, boathouses, and boats; for the construction of gutters and pipes apparently unalterable either above or below ground, even after several years' service; and for a number of other similar purposes the material has already been tried with most satisfactory results—for instance, a large quantity of this material was used for roofing and shedding purposes at the Fisheries Exhibition, where its rain and weather resisting qualities were so well tested as to gain the award of a silver medal. The thinner materials, one-ply and two-ply, are well adapted to the lining of packing cases to keep out moisture, and to wall papering of damp rooms, as an under coat preventing moisture creeping through; whilst waterproof envelopes and stationery and light sample cases and parcel post packages are amongst the other directions in

which this material finds useful application. Canvas and cordage treated by the Willesden process are not increased in weight or rigidity, as is the case when tanned and otherwise treated; whilst a high degree of freedom from mildew, mould, rot, and decay, and greater durability generally are thus secured.

A fuller description of the various uses to which these Willesden fabrics may be put will be shortly given in a paper on the subject to be communicated to the Society of Arts.

#### DISCUSSION.

The CHAIRMAN said he was sure the Society would thank Dr. Wright for bringing before them a very useful application of a very well-known reaction. It was very evident that such a method of waterproofing fabrics and rendering them indestructible must have many practical applications. It was interesting to know from recent experiments made in France with regard to the most effectual method of destroying poisonous germs, that in many cases sulphate of copper exceeded all other disinfectants. Of course in moist climates, where mildew and rot were specially to be feared, these substances treated in the manner described would be practically indestructible. Sleepers had been already pickled with sulphate of copper to a certain extent, but the addition of the ammonium salt with its solvent action on the cellulose, pointed to the possibility of a much wider application of this process.

Mr. TYLER asked whether the thick ropes, samples of which were shown, were waterproofed throughout, or was the exterior only waterproofed.

Dr. WRIGHT replied that the process as applied to ropes and canvas was not so much intended to render them waterproof in the sense of keeping the rain out, as to prevent mildew and rot, to which ordinary canvas was subject. He might call attention to the various specimens exhibited, showing the different effects on strips of canvas, paper, and card, of immersion in water or moist air when treated with this liquid and when left untreated. If the materials were boiled the effect would be still more marked: treated canvas might be boiled for any length of time without any apparent effect of any kind being produced, whilst ordinary canvas would be more or less injured, and of course paper or cardboard would speedily go to pulp. There was another specimen in which several strips of paper had been dipped in the solution for a portion of their length and then passed through rollers, when they became inseparably agglutinated together, and would sustain a much greater weight than before.

Mr. JOHNSON asked if the process added anything to the strength of the card.

Dr. WRIGHT said the amount of strain the material would bear after treatment was very greatly increased, as could be proved by attaching a weight to it.

Mr. NEWLANDS suggested that the same effect would be produced by merely gumming the sheets together. He should like to know if this process was applicable to filtering cloth, and if it would strengthen it. If so, even at a considerable cost, there would be a considerable use for it. Scrim cloth was mentioned, and that was used largely in the sugar manufacture, but it rapidly wore out.

Dr. WRIGHT remarked that there was a great difference between a material formed of several sheets of paper by this process and a piece of pasteboard made in the ordinary manner. The latter (the pasteboard) would be reduced to its pristine elements by exposure to water; but Willesden card would not be affected, the agglutination being permanent. With reference to the possible superiority of the prepared canvas as a filtering material, he was not aware that

it had ever been tried; but he should imagine it would be somewhat less porous than before, on account of the filters being coated with a kind of glutinous cement, which would render the crevices between the warp and woof smaller. But if a somewhat more loosely-woven canvas were treated, it would then no doubt be as permeable to fluids as a more closely-woven kind untreated; and no doubt it would resist the action of boiling saccharine fluids, which he supposed Mr. Newlands referred to.

Mr. EAST asked if it would be possible to treat the material for canvas and ropes before manufacture. That would get over the difficulty just referred to.

Dr. WRIGHT said there was no doubt the hemp fibres might be dipped, but he did not think they would spin so well. If that could be got over by altering the machinery there would be no other obstacle. He should fancy the fibres would be more like bristle after dipping.

#### ON THE FILTRATION OF POTABLE WATER.

BY S. H. JOHNSON.

THERE are few subjects of greater importance to the community in general than the quality of water used for drinking purposes. With the increase of civilisation and the consequent aggregation of the populations into cities and towns, the difficulties have ever increased, in consequence of the pollution of all the readily accessible water by the excreta and refuse of the people. In examining into the subject of water supply it is most striking that, from age to age up to the present, great ignorance as to the transmission of disease by polluted water should be almost universally prevalent, and we do not find until within the present century that our knowledge of the subject has received any important acquisitions. The reason of this is clearly due to the absence of chemical knowledge and ignorance of the inductive methods of research, and although our knowledge of the subject has been greatly expanded during the past fifty years, yet it must be admitted that at present we are only on the threshold of that knowledge which the importance of the subject merits and demands. Intimately connected with the subject of water as a beverage is the zymotic theory of disease, and although the specific organisms producing cholera, diarrhoea, or typhoid symptoms have not been identified, yet the evidences by analogies of results produced, and the similarity of effects of various reagents and conditions on infected liquids are so marked, when compared with like treatment of known organisms, that the conclusion that they are vital organisms, not capable of transmutation, is almost irresistible. However, whether this be so or not, there can be no doubt whatever that the specific poisons producing such diseases are in the vast majority of cases traceable to, and derived from, organic matter in a state of decomposition, and in nearly every instance such organic disease-producing matter has proved to be derived from infected human excreta in sewage, contaminating the drinking water of the persons attacked by the disease named. It is not the object of this paper to do anything further than state these views, about which so much already has been written. It may be taken as granted that the general consensus of scientific opinion is in favour of the idea of the propagation of these diseases by living organisms, and that these organisms are derived from drinking contaminated water. It is well we should have a few striking examples of the evils resulting from drinking contaminated water fresh in our memory before proceeding with the subject of filtration.

**CASE I.\***—In the year 1866 an epidemic of cholera visited London, from which the mortality was, in the eastern district, 3,700, and in the rest of London 660. It has been demonstrated to have arisen in this way: A sailor was landed at Southampton suffering from Asiatic cholera, who went on to London, and it is established that the bowel discharges of this patient passed into the Lea at a point 200 feet distant from one of the service reservoirs of the East London Water Company at Old Ford. There is also conclusive evidence that on several occasions, about this time, this infected water was admitted into the service reservoir without filtration, the supply of filtered water having run short, and this water was distributed by the East London Water Company, and it was found that "the area of intense cholera in 1866 was almost exactly the area of this particular water supply, nearly, if not absolutely, filling it, and scarcely, if at all, reaching beyond it."

**CASE II.**—A district of London on the south side of the river was visited with special severity by Asiatic cholera as often as it had been epidemic in London. On examination it was found that this district was co-extensive and continuous with the district supplied by two of the London water companies who drew their supplies from the grossly-polluted water of the Thames at Battersea—the Lambeth and the Southwark and Vauxhall Companies. These were competing companies, and a duplicate system of mains side by side supplied the houses with water indiscriminately, and in the same streets, in fairly even proportions. In the visitation of cholera of 1848-9 the tenants of each of the companies suffered in about equal proportions. In the next outbreak of cholera, 1853-4, the source of supply for the water had been changed from Battersea to Thames Ditton by the Lambeth Company, and the Southwark and Vauxhall Company continued to draw their supply from the grossly-polluted water of the Thames at Battersea. Here, then, we had an intermingled population, part of whom were supplied with a somewhat diluted and strained sewage, compared with which the remainder might be said to have been supplied with fairly pure water. That portion of the population supplied with foul water had a death-rate from cholera of 130 to every 10,000, and the remainder, who drank the moderately polluted water, had a death-rate from the same cause of 37 to every 10,000, so that the population drinking foul water "suffered  $3\frac{1}{2}$  times as much mortality as the population drinking other water," and there was an analogous correspondence of the deaths from diarrhoea. The number of lives involved in these experiments was 511,000, so that the results obtained are most reliable and conclusive, the two portions of the population being alike in all other conditions with the exception of water supply.

**CASE III.**—The violent outbreak of cholera which took place in the year 1854 in a small district in Golden Square, St. James's, Westminster, by which, within a radius of three minutes' walk of a polluted well, 609 persons lost their lives in the course of a few days. "It was shown by Dr. Snow (1) That the outbreak, properly so called, was principally confined to the area about the Broad Street pump. (2) That 61 out of 73 persons who died during the first two days had been accustomed to drink the pump water either constantly or occasionally. (3) That the water was used in various other ways, and might so have been taken in cases where its use in the ordinary way could not be distinctly traced. (4) That in the workhouse, where the well water was not used, only

5 deaths occurred, whereas 50 would have been a ratio proportionate to that of the neighbourhood around. (5) That in a factory employing 200 people, where the water was drunk daily, 18 people died. (6) That 70 men employed in the brewery in Broad Street never drank the water, and escaped cholera. (7) That in a number of individual instances, which was particularly investigated, the drinking of the water was followed by cholera. In one case a lady living quite away from the district, who had the water sent out to her, died after drinking it. Her niece also died under the same circumstances. (8) That at any point decidedly nearer to another pump the mortality from cholera as a rule ceased, and that in an inquiry extending over 48 fatal attacks which took place nearer to another pump, many apparent exceptions were found to be cases of death in persons who really had a preference for the more distant Broad Street water. (9) That in a particular street, containing 14 houses, the only four which escaped without a death were those in which the Broad Street water was never drunk. (10) That this water was used for drinking purposes only, and was used cold. From all these several facts Dr. Snow is of opinion that the outbreak was attributable to the well water as the medium of dissemination of the cholera poison. He believes, moreover, that the well water must have been not merely generally contaminated by cesspool drainage, but especially with the evacuation of a cholera patient. These conclusions of Dr. Snow have been confirmed in a remarkable manner by Mr. Whitehead, who at first entertained adverse views and investigated the matter independently.

**CASE IV.**—The great unhealthiness of Millbank Prison was for a number of years a source of great anxiety, and many measures were resorted to for its improvement, but in vain. Typhoid fever was especially fatal. At length, in the year 1854, the supply of the prison with water pumped from the Thames was discontinued, and the water raised from the artesian well in Trafalgar Square was substituted for it. Immediately on the introduction of the new supply the health of the prisoners improved, and from that date up to 1872, a period of 18 years, there have been only three deaths from typhoid fever, not one of which was contracted in the prison. Although at previous times the prison was so unhealthy that at one time as many as 500 convicts out of 880 were sick in 1849, and the death rate had reached 82 per 1,000, the average since the Thames water has been replaced does not much exceed 12 per 1,000.

**CASE V.**—At Caterham and Redhill a well-authenticated instance of the pollution of the water supply in a group of towns and villages of the specific poison or organism of typhoid or enteric fever was brought before the Society of Arts in the year 1879, by Dr. Thorne, at the Conference on National Water Supply, Sewage, and Health. It appears that an outbreak of enteric fever occurred simultaneously in this cluster of towns and villages, and 196 persons were attacked within 14 days, 21 of whom died. Since some of the affected districts were quite isolated from the rest, the simultaneous character of the attack in each of the places was very remarkable. This led to an investigation of all the usual conditions likely to affect the case. The sewage and drainage, the means of disposal of excreta and refuse, the milk supply, etc., were each inquired into, but nothing could be found throwing any light on the subject; but, on the contrary, in these matters, there was no condition in common in all the places affected. The single prevailing condition in common in all the places was the water supply; but this was thought to be almost above suspicion, being derived from wells more than 500ft. deep in the chalk. However, in the

\* The cases Nos. I. to IV. are abbreviated from the Sixth Report of the Royal Commissioners (1868) on Preventing the Pollution of Rivers.

infected district there were 1,400 houses which were not supplied by the water from the company's mains, and it was found that not one person was attacked who were occupants of these houses, who had not drunk of the water from the company's mains. This was almost conclusive that it was in the water supply the mystery would be solved. An investigation was made, and it was found that the water company had been constructing an adit between two of their wells at this time, in which a workman was employed who, it was afterwards discovered, was suffering from an attack of enteric fever, and that was also proved, and admitted by this man, and that, notwithstanding the regulations to the contrary, he was compelled to evacuate the diarrhoeal discharges in the adit. The symptoms in the case were well established as those of enteric fever. This quite explained the mystery. There are literally thousands of cases which could be adduced to show that a fruitful source of prevalent zymotic diseases is the drinking of water polluted with organic matter of sewage—indeed, it has been computed that the deaths from this cause alone amount to at least 120,000 annually in the United Kingdom! So that it may be said with truth that England has lost far more by drinking dirty water than by the deaths of all the soldiers and sailors that have fallen in all the battles she has ever fought, and yet England in sanitary matters, and especially in the matter of sewage disposal, is far in advance of every other nation. From the cases heretofore cited, it is evident that when potable water acts as a carrier of infectious diseases, the infection is either derived from, or always associated with, organic matters of animal origin. It does not, however, follow that all animal organic matter contained in water must necessarily be morbid in its effects—rather the contrary is proved by all our experience hitherto. The very fact of the occurrence of epidemics of particular types of disease shows clearly that the existence of infection in a water is not the invariable result of animal contamination, but rather the exceptional condition. In the absence of any known method of determining the presence of infection in water, it is considered that the only safe course is the rejection of such as have an appreciable amount of organic pollution of animal origin. The zymotic theory certainly appears to explain the facts connected with the occurrence and transmission of the class of diseases we have been considering in a way that no chemical theory, when compared with it, can for a moment appear tenable. The assumption that living organisms of intransmutable type and of exceedingly minute dimensions are the cause is being daily more and more strengthened by the researches of biologists like M. Pasteur and others, and the identification of the specific disease-producing ferments and their habits, such, for instance, as that producing splenic fever in sheep, add confirmation to this view. On this assumption the necessity for the presence of certain kinds of organic matter is apparent, as they doubtless form a suitable pabulum for their growth and development, existing like bacteria and other ferments, by breaking down colloid organic matter of complex molecular structure into simpler forms or else into inorganic bodies.

Having now generally stated the grounds for objection to the use of water polluted with sewage for drinking purposes, apart from any sentimental objections, there can be no doubt that the subject is of vital interest to every individual to whom only a supply of more or less polluted water is accessible. With the water supply of our cities and large towns in many cases no exception can be taken. The cities of Liverpool, Manchester, Glasgow, Dublin, and Edinburgh are supplied with upland

waters above the region of any sewage contamination, but London, Birmingham, Bristol, and a large proportion of the smaller towns of the United Kingdom are still supplied with sewage-contaminated water from rivers and surface wells. In London, excluding the district supplied by the Kent Water Company, the average quantity of sewage contamination in the water supplied for drinking purposes is 3 per cent., or about one quarter of a pint of sewage per gallon, an amount that is not pleasant to realise. There is no doubt that the proper remedy is to change the sources of supply from the polluted waters of the Thames and the Lea either to wells in the chalk, the lakes of Cumberland, or the head waters of the Severn basin; but so long as the health and mortality of the people are permitted to be subservient to the interests of capital, it is probable that even in London we shall be obliged to drink water polluted with human excreta. Although in many things the institutions and material welfare of this vast metropolis compare favourably with the best of all that can be found in past history, yet in this matter of water supply we can learn a lesson from ancient Rome—the enormous works which she constructed, the remains of which to this day form a monument to her energy and her just appreciation of the best interests of her people. If the old Romans were here, with all our modern appliances and advantages, this matter of a pure water supply would not have been allowed to linger on account of vested interests, but they would have smiled and done the work. In the paper read by my friend Mr. Hutchinson, on the last occasion of our meeting, he brought before your notice the method by which not only the whole of the solids held in suspension in the sewage of towns can be cheaply and completely got rid of without nuisance, but also a large proportion of the most objectionable colloid organic bodies, by means of precipitation with alumina and lime; and there can be no doubt but that the quality of the London water supply would be greatly improved if the excreta and refuse of all the populations, amounting to 800,000, in the upper Thames basin above the intakes of the metropolitan water companies, were clarified in this way. There would still, however, remain considerable pollution by the surface drainage from highly-manured agricultural lands. So long as we derive our drinking water from sewage-polluted rivers, the method of filtration employed at our waterworks, in the interests of public health, should be the most perfect that our present resources and knowledge can supply. How far the present means employed are adequate we shall now consider. The means employed by water companies for the purification of foul and turbid river water are of the very simplest character, and have undergone no improvement whatever since sand filtration was first recommended by Mr. Telford and Dr. Brand in the year 1828. The water is first collected into reservoirs, where the heavier impurities are allowed to subside, and then, after some days or weeks, the partially clarified water is passed through a graduated filter bed (about 6 to 8 feet deep) composed generally of successive layers of boulders, large stones, small stones, coarse gravel, fine gravel, and lastly one or two grades of sand. Through such a filter bed the water is permitted to pass at the rate of from 3 to 9 inches in depth per hour—that is to say, from  $1\frac{1}{2}$  to  $4\frac{1}{2}$  gallons per square foot per hour. For Thames water the latter speed is considered much too fast, because it is found that if the rate much exceeds 5 in. per hour some visible suspended solids pass through the filter. Thus an acre of the filter beds so prepared is capable of filtering from 60,000 to 100,000 gallons of water per hour. It has frequently been asserted

that a considerable proportion of organic matter in solution is oxidised and converted into nitrates and nitrites, but that this is not the case is evident by comparison of the water of the London companies after subsidence and before filtration and after filtration through the filter beds.\*

Names of Companies.	Nitrogen as Nitrates and Nitrites. Parts per 100,000.	
	After Subsidence but before Filtration.	After Filtration.
West Middlesex .....	229	335
Grand Junction .....	356	315
Southwark and Vauxhall .....	318	315
Laubeth .....	318	361
Chelsea .....	312	397
New River .....	310	310
East London .....	311	311
Average of 7 .....	330	327

From this table it appears that the average result of filtration of the seven companies' water who use filter beds in London shows that the oxidising effect is practically *nil*, the water having, if anything, less nitrates and nitrites after filtration. From these figures it is evident that there is nothing in the nature of surface oxidation takes place by reason of the water being brought in contact with air in the pores of the filter. It is manifest that the removal of organic matter is simply mechanical, and that the organic matter removed was simply in suspension. It requires but little consideration that one may be convinced that a sand filter is at best a rude contrivance to employ for so delicate an operation as that of filtering the excessively fine matter in suspension at times in river water; and were the case dependent on and governed by the size of the pores or interspaces between the particles of sand alone, such a filter would be altogether inadmissible. But when it is considered that the difference in the dimensions of the particles of sand and the invisible particles which give to water an opalescence is very great, and that in fact the interspaces in the sand filter are reservoirs in which the fine particles of solid matter can subside, then it is more simple to comprehend its operation. It has been found that water with a turbidity from very fine suspended matter cannot in any reasonable time be clarified sufficiently by simple subsidence in a waterworks reservoir, and notwithstanding this it can be clarified quickly by a sand filter. On the assumption that the upper surface of each grain of sand becomes a catchment shelf for the suspended matter deposited on it, the *modus operandi* is clear. We may to this end consider a filter bed as a modified subsidence reservoir having two altered conditions—namely, a greatly-extended area, and a greatly-diminished depth. Now, if any of you will take the trouble to observe, if you have not already observed the fact, you will find that the time required for matter in suspension in a fluid to completely subside is in the direct ratio of the depth of the vessel—that is, the deeper the vessel the longer time it will require. For the sake of expressing the case numerically we will assume that we have a filter bed of three acres area, the sand in which is 50in. deep, and that the interspaces between the grains of sand average 0.1in. in

depth; that there is an average of 20 such spaces to the inch depth of the sand of the filter bed; that the area of the available catchment shelves on the upper surfaces of the grains of sand in each of these twentieths of an inch is one-third of the area of the upper surface of the filter bed. Then we have—

$$\frac{20 \times 50 \times 3}{3} = 1000$$

acres, equal net area of catchment shelves, so that the filter bed is equivalent to a subsidence tank of 1,000 acres in extent,  $\frac{1}{1000}$ th of an inch deep. If we now compare this with a subsidence tank 100in. deep, and bearing in mind the fact that the time required for subsidence of suspended particles is proportional to the depth, the matter would be deposited completely in the filter bed in  $\frac{1}{1000}$ th of the time required for deposition in the subsidence tank 100in. deep. It is simple thus to understand the action of a sand filter in removing a slight turbidity in water. And it will now be readily understood how that a very slight increase in the rate of flow of the water through a sand filter will be sufficient to carry the deposited matter through the filter. Thus the work done on a given area of filter bed is of necessity limited, and hence the necessity for large areas of sand filters. If we consider the great importance of this subject of the filtration of water at our waterworks, and that it is in the solid matters in suspension that all the danger exists (for we cannot conceive it possible that the disease-producing organisms can exist absolutely in the liquid state), it would seem more desirable, if a positive filter of so fine a porous texture were used, that it would hold back mechanically all insoluble organic matter, however fine. The Porter-Clark process for softening water, which Mr. Porter so amply brought before the notice of the Society at the last meeting, much more closely approximates to this condition than a sand filter, by making use of the fine precipitate of carbonate of lime, after the softening is effected by Clark's process, as a filtering medium for the water. This is evident by the disappearance of the yellow tint due to organic matter, and present in all the London waters, and by the beautiful blue of pure water which then becomes apparent. If this process of Mr. Porter's and Dr. Clark's were substituted for the present crude and imperfect subsidence tank and filter bed, there can be but little doubt that not only would the water supply of London, or any other large town where it is required, be greatly benefitted, but it is very probable that a positive economy would result to the water companies. Although a supply of better and purer water is much to be desired, yet that alone is not sufficient protection, and so long as the present system of house cistern and intermittent supply exists additional safeguards should be employed; and in country places and villages, and towns where the water is supplied from surface wells, a good method of purifying drinking water for household use is much to be desired. If all the cases of sickness, and the maladies of various kinds which are directly traceable to the contamination of water in household cisterns, could be recorded for a single year, there is little doubt that a revelation of sickness and death from this cause would be produced only a little less astounding than that arising from poisoning with sewer gases. There are but few individuals who cannot refer to well-authenticated instances where illness affecting a household has been traced to the water cistern. It may be that the decomposed remains of a dead bird, mouse, or rat is found in the cistern, and that the mysterious illness disappears after the cleansing which then ensues. Even decaying vegetable matter, such as leaves, or the successive

\* The data for this table are taken from the 6th Report of the Commissioners appointed to Inquire into the Pollution of Rivers.

generations of vegetable growths which occur in some water mains and cisterns, are not unfrequently the source of distressing maladies, and although the necessity for scrupulous precautions to secure a pure water supply from the household cistern has been urged from time to time, yet, like many other things which are not apparent at first sight, do not obtrude themselves on our senses, no attention is paid to the subject. Things which can be seen, or discovered by the palate, at once arouse suspicion and vigorous action. Many of us would be up in arms if we found our milk watered, or our coffee mixed with chicory; but from a sanitary point of view these are venial matters compared with impure water. Daily we are in the habit of straining at the gnat and swallowing the camel in sanitary matters, and not the least in this matter of household water.

It is our object now to consider generally the various methods hitherto used for filtering water for drinking purposes in the household, and in a very brief way to examine how far they meet the requirements. All existing types of water filters may be classed under two heads: (1) *Mechanical filters*, which separate mechanically suspended solid matter from water. (2) *Chemical filters*, which have the property of removing certain bodies, such as albumen and some salts, in a more or less perfect state of solution, in consequence of a specific attraction which some bodies possess, depending on their molecular constitution, or, chemically speaking, on the particular kind of matter which forms the filter, such action not depending on the size of the pores. Mechanical filters remove the solids, because the pores are too small to permit anything but liquid to pass, and they have hitherto been made of textile or felted fabrics of every description, the pores of which are fine enough; coarse pottery or earthenware in the biscuit or unglazed state; sandstone, in various forms, particularly that called dripstone; carbon diaphragms or blocks formed of powdered coke, cemented together by means of carbon deposited by heat from sugar or tar in closed moulds; wood in thin sheets; leather; layers of finely-powdered substances, such as glass, sponge, and, perhaps most effectual of all, paper. It is not necessary to enlarge on this class of filters. Chemical filters for animal charcoal and spongy iron are the principal chemical filters employed.

The annexed analytical tables, showing the effect on the organic impurities by employing animal charcoal and spongy iron respectively, have been taken from the 6th Report of the Rivers Pollution Commissioners. It will be seen that the organic constituents of water, even that which has already been filtered through a sand filter, undergoes a further very considerable reduction with both spongy iron and animal charcoal. The spongy iron is used in porous blocks, and the animal charcoal in coarse grains, and the water is passed through a small vessel filled with it. The great defects of these filters are that (1) they are bad mechanical filters, and (2) the water has to pass through the accumulated impurities of many months, and in the case of animal charcoal, owing to the presence of phosphates in large quantity (animal charcoal consisting of charcoal 10, phosphates, etc., 90), it is very favourable to the growth of low forms of vegetation and afterwards animal life. In the 6th Report the Commissioners state: "Indeed, we found that myriads of minute worms were developed in the animal charcoal and passed out with the water, when these filters were used for Thames water, and when the charcoal was not renewed at sufficiently short intervals. The property which animal charcoal possesses in a high degree of favouring the growth of the low forms of organic life is a serious drawback to its use as a filtering medium for potable waters." It has been found in

consequence of the accumulated impurities that when water is passed continuously for a long period through such porous masses, that at length the water will actually be further polluted in passing through the filter.

The essential requirements of a good household water filter are: (1) It must be a perfect mechanical filter. (2) It must be an active chemical filter. (3) It must be easily accessible for examination and cleaning. (4) It should have sufficient filtering area to supply the necessary quantity of water without delay or inconvenience. (5) The filtering medium should be replaceable with great facility, so that there should be no excuse for neglecting this precaution. (6) The arrangement should be such that nothing but pure water could be conveniently used, either for cooking or for drinking. The author having these objects in view, has endeavoured to meet all the conditions in the following way: the filtering medium

employed consists of thick sheets of filtering paper, the peculiarity of which is that, instead of being made of ordinary paper pulp alone, a quantity of pure animal charcoal, freed from phosphates by washing with acid, is added to the pulp before it is formed into sheets. From 10 to 20 per cent. of this paper consists of purified animal charcoal. This special paper is used in a small filter press, worked by means of the pressure in the main service pipe, either in the basement of the house where the water comes in, in case of constant service, or else in the service pipe from the supply cistern in the case of intermittent service. By an inspection of the specimen filter shown, the arrangement of the filter will be readily understood. The filter press employed for this purpose, and which is shown as mounted for use, consists of a series of grooved plates on which the diaphragms are supported. The grooves in the filter plates forming the drainage surfaces, each plate has both surfaces grooved or channelled, and provided with the prepared carbon paper. These plates, with their filtering papers *in situ*, are kept apart from each other by an open frame or distance ring, and thus a battery of

filtering cells is made up, when the series of alternating plates and frames is screwed up between the fixed and loose heads of the machine. Passages for inlet and outlet are formed in the metal of the plates and frames, and suitable ports are formed so that the supply ports shall be in the distance frames conducting the water to be filtered between the paper linings of the filtering cells, and outlet ports conduct the filtered water into the common outlet channel from the grooved plates. The method of forming the internal channels in a pressure filter was originally devised by Danek. Fig. 1 shows the filter mounted against a wall filtering all the water in a service main. Fig. 2

FIG. 1.

shows the filter mounted vertically, where it may be more convenient to draw off in front in that position. When it is desired to change the carbon papers for fresh ones, the filter can be shut off on both sides from the service pipe by means of the two valves, the main tightening screw can be loosed, then all the papers become free to be removed and replaced, which is only the work of a minute or two. When screwed up the machine is again ready for work. We thus have (1) a good mechanical filter of paper with the pores filled in with fine carbon; (2) a good chemical filter with the carbon in it ten times more concentrated and

FIG. 2.

more active than ordinary animal charcoal in grains, in consequence of its being deprived of the phosphate of lime, and by the absence of which it is no longer capable of favouring the growth of the animal and vegetable organisms, which are the chief danger of the phosphatic animal charcoal in grains. (3) Nothing can be more simply accessible for cleaning, all the parts being released by means of a single screw. (4) The filtering area, even in a small apparatus, is very considerable. A machine with 6 plates has 12 filtering papers, and these working under the pressure of the main admit of the water being drawn off as required, without the necessity of the objectionable practice of keeping a store of filtered water. (5) The filtering medium in the form of these thick

paper discs can be changed with the greatest facility. By this means passing the water to be filtered through the accumulated impurities of a long period is easily avoided. No doubt, the masses will have to be educated to a knowledge of the impurity of the water they drink, and the vast amount of disease and suffering in consequence, and then it will not be thought superfluous to pay daily attention to secure clean drinking water. I had hoped to be able to give you some practical results of the working of this system, and the analytical results of the water before and after filtration, but it has not been found possible to accomplish this. But with the permission of the Society I may have an opportunity of making a short communication at a future time on this subject.

## DISCUSSION.

The CHAIRMAN said they had to thank Mr. Johnson for bringing forward an excellent method of applying the filter press to drinking water, but with regard to the general question one must remember, in justice to the much-abused water companies, that the health of London did not seem to suffer from the river water, in fact, it might be open to question whether sufficient area, especially with the presence of vegetable growth, did not afford as much safety from serious pollution as wells—at any rate unless they were extremely deep; and judging from a case which had occupied the law courts recently there seemed to be two sides even to the deep-well question. Whatever the water supply, it was necessary that it should be filtered for the purpose of drinking, and there was in this system a very perfect means of doing so, perhaps not so perfect as the combined chemical mechanical action of the Porter-Clark process, but one infinitely superior to the average of filters, some of which he had examined from time to time, and found they did not require a more delicate test than the nose to discover that the water was much better before it went in than after.

Sir FREDERICK BRAMWELL said it might interest the meeting to know, with regard to the case referred to in the paper of the pollution of water at Caterham, that there was one convincing proof of the theory advanced, and that was this: a portion of the district supplied by the Caterham company nominally was free from the disease, and it was asked how could that be if the disease was due to the water, but it turned out that that particular portion of the district was for a time supplied by another company, and, so far as the mains were supplied by that other company, there was no disease, whilst those supplied from the well in which that wretched man committed the filthy act mentioned the disease was rampant. That it must have arisen from the water was also clear from another fact. A lady drove over to Redhill, and while she paid a call there, and left her carriage standing in the town, the coachman got down and drank from the public drinking fountain, went home, and in a few days was dead. It could not therefore be anything in the locality, since here was a fatal result to a stranger who was only in the place perhaps half an hour. One must remember that this had really nothing to do with the question of deep well water or not. The water so-called, which had been supplied many years before, and many years since, was amongst the purest of the deep chalk waters, and the evil arose from an accident in one sense which might have befallen the New River. It had nothing to do with the source of supply. The general question had been touched upon in a way which was often done, and a great deal had been said about the iniquity of London water companies. Now, in the autumn of 1883, whilst travelling in the United States, he made it his business in every town to

which he went to inquire about the water supply, and he was assured by all the engineers to whom he spoke, with one exception, the village of Poughkeepsie, that there was not a single instance of the water being filtered before it was supplied to the towns. When he asked how that was, he told him that they all had filters in their own houses. Then he asked about the poor people, and those who lived in tenements, and those who had not filters, and he replied that they had not thought about them. He told him that if ever there was an epidemic of cholera there the loss of life would be something frightful. In New York the consumption of water was 80 American gallons (equal to 64 English gallons) per head per diem, but the population had so grown, and the mains were so overtaxed, that the terminal pressure was next to nothing, and you saw in the shop windows hydraulic engines to be put into the basements of houses, to be worked from the feeble pressure from the mains in order to pump up the balance of the water to the top of the building. That was how it was dealt with there, because they dare not enforce proper fittings on the customers, because the popular voice did not like it. In Boston the water was so abominable that every person of respectability purchased it from a private company who brought it round in casks. To come back to London, there was an unimpeachable source of supply in the Kent Waterworks, and he thought also an unimpeachable source in the New River. They had heard tales about the intake of the New River which proved to be untrue, and with regard to the supply from the Thames, chemistry had failed to indicate any source of disease. Dr. Frankland said so far as he knew no harm arose from drinking healthy sewage, but, of course, if any outbreak of disease arose it might be that evil would follow. Were they to buy up the present companies? In that case he supposed a miracle would happen, as had constantly happened before. You might go into a committee room in the House of Commons and find a number of gentlemen there, including the town clerk and mayor of the town, declaring that of all the vile supplies of water in creation the one supplied by the company was the worst; then they brought forward the joking witness, the scientific witness, the oldest inhabitant, and so on, and at last they made such a dreadful case that the committee suggested to the company, had you not better agree with the corporation. Then they went out into the lobby and came back and said it was settled. The corporation acquired the undertaking, and without any change of any kind, except the mere fact that the company was purchased by the corporation, that dreadful water, which was not fit to be drunk, or even to be looked at, became proper water for the town to drink for ever afterwards. That was a miracle of very frequent occurrence, and he supposed the same thing would happen in London. It might be said that he was only airing the fallacies of Mr. Easton and Mr. Bazalgette, but that fallacy was this: There were used for all purposes, in London, 32 gallons per head per diem, including waste of all sorts, a great deal of which arose from bad fittings, and they were allowed to exist because of the outcry which would arise if they attempted to enforce the use of good fittings. By no possibility could the people use more than two gallons per head per diem for potable and culinary purposes. The experiment had been carefully made, and therefore with four million persons in London the necessary supply for those purposes would be eight million gallons per day. People at once said, What, would you have a dual service, with all the terrible expense and complication? In other towns it was done, in Paris there was a triple service. To

his mind the mistake was in not keeping water for potable and culinary purposes separate. The water for watering the roads and so on did not require to be of such absolute purity, and he thought it would be extremely well at the cost of some five millions to appropriate the chalk water supplies to cooking and drinking purposes by a separate system of mains, and to use the other water, which was quite good enough, for all other purposes. The question would then become very simple. There was ample water in the chalk for drinking purposes for a London of double the size, but he did not think there was ample water in the chalk within a reasonable distance for the supply of the whole metropolis under the present system. Then he would suggest that this dual supply should be made use of for the purpose of extinguishing fires, and this was by no means so absurd as some people seemed to imagine. The whole of the water used in London for extinguishing fires amounted, according to his recollection, to about a day's supply. It was said that it would be using the most expensive water for extinguishing fires, but that would not matter. They could afford to pump eight million gallons of water a day against a head of 400ft., and with that head and a proper system of pipage they could contribute the greatest quantity of water ever wanted for the greatest fire ever known, taking Captain Shaw as an authority.

A MEMBER asked if Mr. Johnson claimed that the filter press would take out germs from the water, and if so how he arrived at that conclusion, because he had already stated that he did not know what the germs were.

Mr. JOHNSON, in reply, said he had stated in the paper that the object was not to take the germs out, and no one could say that it did. The principal thing was to remove organic matter, because it was found, whether the disease proceeded from germs or merely from some specific poison, it was always associated with organic matter. That was the reason why animal charcoal was introduced into the filtering paper. Further, the removal of phosphates was an important matter, as it deprived the lower organisms of the food necessary for their existence, and therefore there was not the opportunity of the accumulation of a mass of decomposing organic matter in the filter itself. With reference to the fact stated by the President, that London was very healthy, he would simply remark that it might be healthy as compared with other towns, but still it was not so healthy as it would be if perfectly pure water were supplied, because there was a great deal of disease resulting from the drinking of bad water, as could be testified by any medical practitioner.

## NOTES ON KIESELGUHR AND ITS TECHNICAL APPLICATIONS.

BY A. HAACKE.

KIESELGUHR, or infusorial earth, is a white, gray, or greenish powder of very low specific gravity, consisting chiefly of the minute silicious shields of diatomacea, the beautiful and varied forms of which will be known to everyone familiar with the use of the microscope. Large deposits of fossil diatoms have been traced in many parts of the world, and several mines producing kieselguhr are worked in Europe, but the largest, and those yielding kieselguhr of the purest quality and lowest specific gravity are situated near Naterleuss station, on the railway from Hamburg to Hanover. The kieselguhr is found there from the surface down to a depth of about 150ft., being covered only by thin beds of diluvial and alluvial origin. The upper stratum of this large deposit supplies the white kieselguhr

This quality contains very little organic matter, but some sand; therefore, after being washed it gives a very pure and porous product. The second stratum produces gray kieselguhr, containing very little sand, but sufficient organic matter for calcining it, and the product then is kieselguhr of perhaps the finest quality existing. If the exertions of colour manufacturers to make a colour which will really be imperishable under the influence of strong acids are to be crowned with success, this perhaps is the material which might lead to satisfactory results. The lowest and by far the largest stratum, varying from 50 to 100 feet in thickness, supplies the green kieselguhr, which contains up to 30 per cent. of organic matter, showing clear imprints and fragments of fishes, well-preserved fir cones, leaves, bark, and twigs of birches, firs, etc. In order to utilise the immense deposits of green kieselguhr, kilns have been erected for burning or calcining same. When dry, this material glows like turf or peat, and this is utilised in the calcining process. The kilns,

important property of kieselguhr, which it owes entirely to its great porosity, is its high non-conducting power. All porous materials are more or less non-conductors, and those are the best which contain in a given square the greatest number of minute cells, enclosing air, which is prevented from circulating. The cooling of heated bodies may be effected by three methods—by radiation, by contact of cold air, and by conduction. A closed air space around a vessel containing high heat is already a good protection, but if the space, instead of with air, were filled with powdered kieselguhr, say 2in. thick, the insulation would be almost perfect, for the radiation would be totally prevented. The air contained in the kieselguhr would be warmed in a few minutes, but being unable to circulate it would be prevented from giving its heat off. Conduction would be impossible, as the following test will show. If a piece of kieselguhr 2in. long, by means of a blowpipe, is heated to white heat on the one end, no increase of heat will be

simple round furnaces, about 15 feet high by 6 feet diameter, are filled and lighted at the bottom, no additional fuel being required to keep them going. They are continually replenished with green kieselguhr at the top, and the calcined taken out from the grates underneath. The product is perfectly free from moisture and organic matter, and has therefore a much higher market value than green kieselguhr. Its reddish colour is due to some traces of oxide of iron. Kieselguhr has many valuable properties, which adapt it admirably for various industries. It consists almost exclusively of silica, and is therefore in its pure state as fireproof as any material in the world. It resists the action of the strongest acids, but it can be easily made to melt after being mixed with an alkali or some sort of alumina. Even by boiling under pressure combination may be effected. Silicate of sodium or water glass has been made of it in this way, but white sand is now generally used for this article, because kieselguhr has risen considerably in price, and owing to its low specific gravity very large melting pots had to be employed. Its great porosity, although a drawback for this particular industry, makes it very valuable for the manufacture of dynamite. German manufacturers have at times produced dynamite of 82 per cent.—namely, 18lb. of kieselguhr were able to absorb 82lb. of nitro-glycerine, and keep it in a firm paste, which did not allow any nitro-glycerine to escape. In England only 75 per cent., i.e., dynamite, is allowed to be made or sold; therefore the green kieselguhr, after being calorised, is best adapted and generally used for this purpose. A very

noticed on the other end. Kieselguhr is now being used by safe makers, cooking stove and kitchen manufacturers, to make fireproof rooms and doors, for filling up bulkheads in steamers, etc. Glass manufacturers use it for annealing, and no doubt the more it becomes known the more will opportunities be found for adopting its use. Its high non-conducting qualities, together with its property of melting when mixed with a slight percentage of alkali, has induced Dr. Frank, of Charlottenburg, in conjunction with Mr. Berkefeld, to take out patents for the manufacture of fireproof refractory bricks, slabs, etc., of very low specific gravity. The present specimen is not quite perfect yet, as the experiments have not been brought to a close. There seems, however, but little doubt that these bricks will be of great importance for the setting of steam boilers, the lining of blast furnaces and the hot-air pipes connected with them, for the backs of fireplaces, and for all purposes in general where it is necessary to prevent the partial escape of heat before being utilised. Small rods are formed of the same material. These are used for absorbing a new disinfectant, namely, bromine, which thus solidified takes 72 times as long to evaporate as in its natural state as a liquid. The small rods saturated with bromine are supplied and kept in glass bottles, which have only to be opened to allow the bromine vapours to escape. I am not aware whether this article is known already in England in this form, but shall be glad to give further information to anyone interested in it. The non-conducting capacity of kieselguhr is

without doubt the highest in its natural state of a powder, but as in this form its application to steam-heated surfaces presents certain drawbacks and difficulties, a composition has been made of it, for about five years past, which can be applied direct to steam-heated surfaces, and is known under the name of kieselguhr, or fossil-meal composition. The amount of heat lost from steam-heated surfaces is hardly fully estimated. Some tests made by the National Smoke Abatement Institution lately, and published in the *Engineer* of January 25th, 1884, fols. 65-66, give valuable information regarding this. A 5in. steam-pipe, 36ft. long, filled with steam of about 55lb. pressure, condensed in 42 hours 2,327·4lb. of water; and another one of same dimensions, but covered  $\frac{1}{2}$ in. thick with some fossil-meal composition, gave 613·2lb. of water, showing a saving of 1,714·2lb., or if 1lb. of steam coal had been used to evaporate 8lb. of water into steam

$$\frac{1714 \cdot 2}{8} = 214 \cdot 2 \text{ lb.}$$

of steam coal were saved in 42 hours, or in the year, if the pipe were hot day and night,

$$214 \cdot 2 \text{ lb.} \times 208 = 44,553 \cdot 6 \text{ lb.}$$

or nearly 20 tons of steam coal were saved. The surface of the bare pipe measured 615 square feet. There are many more industries in which kieselguhr might be used with advantage now that large and regular supplies are attainable. It is used by manufacturers of ultramarine, by soapmakers; a composition for preventing rot and fungus in buildings is made of it; it is a splendid polish for metals, etc.; it could be used for making artificial meerschauum, porous pottery, an equivalent for animal charcoal, etc.; and if chemists and manufacturers would experiment more with it, very likely many other uses for it would be discovered.

I have been reminded since I have come into the room that the absorptive property of kieselguhr has been utilised by Messrs. Vorster and Grüneberg in a patent taken out in Germany. What is termed "dry sulphuric acid" is prepared by saturating dry and finely-divided kieselguhr with three or four times its weight of 66° sulphuric acid. The product, which therefore represents at least 75 per cent. of its weight of absolute acid, is said to retain the pulverulent form, and the advantage claimed is that in this condition it can be transported by land or sea in lead-coated sheet iron vessels without damage of breakage. This being so, there are many obvious applications of the saturated kieselguhr.

MR. E. K. MUSPRATT IN THE CHAIR.

## THE LOSS OF NITRE IN THE MANUFACTURE OF VITRIOL.

BY GEORGE ESCHELLMANN, PH.D.

It has always been an important question to the practical and theoretical chemist to account for the losses of nitre in the manufacture of vitriol. To the former on account of the great value of it, to the latter on account of the interesting reactions taking place between sulphurous acid, nitrous gases, oxygen, and steam. Theoretically the same quantity of nitre should convert an infinite quantity of sulphurous acid into vitriol, provided no losses take place; and in order to reduce them as much as possible various improvements have been introduced in this manufacture. To trace out these losses in the various stages of the process is the object of this paper, and all experiments mentioned have been made on the vitriol chambers in our works (James Muspratt and Sons) in Widnes, and Mr. E. K. Muspratt has kindly allowed me to use such figures as would be useful to my purpose. The losses of nitre are of two kinds first, mechanical losses, such as nitrous gases kept in solution by vitriol used for salt-cake making, and

### No. 1 SYSTEM.

### No. 2 SYSTEM.

	Chamber Space— cubic metre per kilo. of S.	Nitre used— per cent. on S.	Oxygen at Outlet, per cent.	Unabsorbed of nitre used per cent.
Quarter I. ..	1·34	3·21	6·1	12·02
Quarter II. ..	1·47	2·75	7	12·5

nitrous gases escaping unabsorbed at the Gay-Lussac tower and through leakage of the chambers, which latter, if any, should not exceed 2 per cent. of the total loss; secondly, chemical losses through reduction of nitrous gases to nitrogen and nitrous oxide, which compounds are lost to the process. The mechanical loss at the Glover tower is in the vitriol for salt-cake making. An average sample taken from it was 130° Tw., and analysed took 3c.c. of  $\frac{1}{10}$  normal permanganate solution per 10c.c. of vitriol; but permanganate oxidising sulphurous acid as well as nitrous anhydride, the same sample was tested in the nitrometer, where it showed no appreciable reaction, consequently the permanganate was used for oxidising sulphurous acid and arsenious acid, and no nitrous anhydride was present. The mechanical loss by non-absorption of soluble nitrous gases at the Gay-Lussac tower was found out by means of a continuous test of the escaping gas. The gas was drawn by a Bunsen pump through the absorption bottles, and measured by a gas meter. To absorb the gas, it was drawn through a measured quantity of pure vitriol of 1·84 specific gravity, which absorbs all soluble compounds of nitrous gases, and part of this was tested in the nitrometer. Simultaneously a second continuous test was taken by means of an aspirator, all soluble compounds absorbed by caustic solution, and the remaining gas was tested for oxygen. Thus knowing the amount of oxygen and the quantity of pyrites burnt, it is an easy thing to calculate the amount of gas

escaping in 24 hours from the system. In our works we have two Gay-Lussac towers, each one connected with a system of chambers burning about the same quantity of pyrites. This test is taken regularly every day, and therefore I am able to give average results for several quarters, as shown in accompanying table. Besides the loss of soluble nitrous gases a certain amount of nitric oxide escapes at the Gay-Lussac tower. To test it the same continuous test as applied to the estimation of the soluble gases was used. The gas was first drawn through strong pure vitriol, of 1.84 specific gravity, to absorb all soluble nitrous gases, then passed through two bottles filled with caustic solution to absorb any sulphurous gas, and then drawn through four bottles filled with permanganate solution and great excess of sulphuric acid. I found it necessary to divide the permanganate solution into four bottles to oxidise all nitric oxide in the escaping gas, on account of the small quantity in it. The nitric oxide is oxidised to nitric acid, and after a duration of 24 hours for each test the contents of the four bottles were collected, the excess of permanganate reduced by a proto-iron solution, and a measured quantity of it boiled with a weighed quantity of double-iron salt. The excess of double-iron salt was titrated back with permanganate solution, and then the quantity of nitric oxide per number of cubic feet was obtained by calculation. This loss in a great number of tests came to 7 per cent. with the chamber space of 1.47 and 7 per cent. of oxygen. The variation of all tests was within 6 and 8 per cent. Therefore the mechanical losses amount to 22 per cent: (1) At Glover tower, trace below 1 per cent. (2) At Gay-Lussac tower, 19 per cent.; (a) through non-absorption of soluble gas, 12 per cent.; (b) through escape of nitric oxide, 7 per cent. (3) Through leakage, etc., 2 per cent. It will be necessary to add that the amount of sulphur going away at Gay-Lussac tower was below  $\frac{1}{2}$  per cent. of the sulphur charged at the kilns. The two Gay-Lussac towers were 1.6 per cent. of the total chamber space, and the strength of the nitrous liquors was about 1 per cent.

I think it will be here the best opportunity to mention what Prof. Lunge and Dr. Naef have found out about chamber escapes in the vitriol process, published in the German *Chemical Industry*, January, 1884. Dr. Naef worked the chambers very yellow, and testing the escapes then found no nitric oxide, no sulphurous acid, but a large quantity of soluble nitrous gases, amounting to 50 per cent. of the total loss; and also there was a certain quantity of nitrogen dioxide present in the gases entering the Gay-Lussac tower. Keeping now the chambers too light—that is to say, a relatively large quantity of sulphurous acid entering the tower—the escape of soluble compounds was reduced to traces, and 22 per cent. of the loss as nitric oxide found in the escapes. Although the first figure seems to me very high it shows evidently that working chambers with either extreme nitrous or sulphurous acid nitre is lost considerably in both cases. In the first case it is lost as nitrous anhydride, in the second as nitric oxide. In ordinary working chambers with a slight escape of sulphurous acid there is no nitrogen dioxide present, but always, as shown previously, a certain amount of nitric oxide (7 per cent.), which is lost. Consequently the best way to avoid losing much nitre at the Gay-Lussac tower is to have all nitrous gases entering it as nitrous anhydride—no mono- or di-oxide being present at all. This can be obtained in keeping the chambers very rich in nitre, allowing no appreciable amount of sulphurous acid to enter the tower, and thus having only nitrous anhydride and nitrogen dioxide; the latter must be reduced by adding sulphurous acid

sufficient to reduce it to nitrous anhydride. If the correct amount of sulphurous acid could be insured this process promises to save nitre. Besides this process, known as Messrs. Benker and Lasne's, the increase of chamber space will give the same result as regards the gases entering the Gay-Lussac tower. It converts all sulphurous acids into vitriol without great excess of nitre and gives the nitric oxide time for oxidation.

So far the losses of nitre accounted for come to 22 per cent., using 2.75 per cent. on the sulphur burnt, and with 1.47 cubic metre of chamber space per kilo. of sulphur. The chemical losses can only take place through reduction of nitrous gases to either nitrogen or nitrous oxide, which gases are insoluble in strong vitriol, and lost to the process. As we have no proper reliable test for nitrous oxide, and estimation of nitrogen produced by reduction being out of question, I was only able to show by experiments made on vitriol chambers under which conditions these reductions are likely to take place. The question of reduction in the Glover tower has been the object of several papers, and theory and practice have come to the conclusion that there is not much, if any. In the Glover tower we have nitrous vitriol or nitric acid going down and meeting hot sulphurous acid and air. No reduction takes place below 200° C., according to Professor Lunge's paper published in *Dingler's Polytechnic Journal*, vol. 225, 1877. The highest temperature of the vitriol running off the tower which I have observed was 150° C. The only possibility is just at the inlet of the gases from the kilns, but when the vitriol reaches that part it is already denitrated. The upper part denitrates, the lower part boils down, and the reaction in the tower is represented by—

According to Professor Thomsen's book, "Thermochemical Investigations," the heat produced for  $\text{H}_2\text{SO}_4$  by sulphurous acid, oxygen, and water, is 53,480 calories. In the first chamber drips are generally kept about 130° Tw. This corresponds with the formula  $\text{H}_2\text{SO}_4 + 2$  parts water. According to the same authority 9,418 calories are evolved in combining  $\text{H}_2\text{SO}_4$  with 2 parts water, therefore this produces a total quantity of 62,898 calories. For 134 grms. sulphuric acid of this strength 54 grms. of water must be introduced, and this is done generally as steam of 125° C. 1 grm. steam of 125° C. contains 64,625 calories—thus 54 grms. = 34,809 calories. Assuming the quantity of steam to be increased by  $\frac{1}{2}$ —that is, producing  $\text{H}_2\text{SO}_4 + 3$  parts water—then 18 grms. of steam of 125° would be required in addition. 18 grms. steam contain 11,603 calories; to combine ( $\text{H}_2\text{SO}_4 + 2$  parts water) with 1 part water = 1,729 calories are evolved. The temperature of the first chamber will be of an average of 50° C., therefore the steam will be cooled to 50° C. 1 grm. water of 50° contains = 50,087 calories; 54 grms. contain = 2,704 calories; 18 grms. contain = 901 calories. Thus for 54 grms. 34,809 - 2,704 calories = 32,105 calories, would be evolved; and for 18 grms. 11,603 - 901 = 10,702 calories, would be evolved. Further, for  $\text{H}_2\text{SO}_4 + 2$  parts water would be therefore evolved, for reaction = 62,898; from 3 parts water as steam = 32,105; total, 95,003. For  $\text{H}_2\text{SO}_4 + 3$  parts water = 95,003 + 10,702 + 1,729 = 107,434, would be evolved. Then having for 100 volumes per cent. of gas entering the chamber containing 6 volumes per cent.  $\text{SO}_2$  and 94 per cent. of other gases, in the first case 3 x water = 18 volumes per cent., must be introduced; in the second case 4 x water = 24 volumes per cent. Thus we have for 118 volumes evolution of 95,003 calories; for 124, evolution of 107,434 calories; or for equal volumes (1) 95,003 : 118 = 805 calories; or for equal volumes (2) 107,434 : 124 =

867 calories. The temperature excess of the first chamber over the air is proportional to the quantity of heat evolved, the temperature of the chamber being  $50^{\circ}\text{C}$ ., and producing vitriol with three equivalents of water evolve 805 calories per unit of volume, and have an excess of temperature over air of  $50 - 15 = 35^{\circ}$ . Increasing the steam by one equivalent, and producing 876 calories per unit, we have the following proportion to ascertain the increase of temperature:  $805 : 867 :: 35 : x$ .  $x = 37.6^{\circ}$ . Consequently an increase of steam by one-third would raise the temperature in the first chamber by  $2.6^{\circ}\text{C}$ ., but such variation never happens in well-working chambers. I come therefore to the conclusion that the variation of temperature caused by variation of steam can be entirely neglected, being practically none. The variation of the temperature caused by the surrounding air I found to be within  $5^{\circ}\text{C}$ . in 24 hours, increasing towards the warmer part of the day; and this variation will be rather lower in winter, when the variation of the outside temperature is generally less than in summer.

The only source for variation of temperature is the formation of vitriol, and therefore we have in the observation of the temperature always a quick indicator of the quantity of vitriol made in the first chamber. This quantity depends to the greatest part on the quantity of nitrous gases present, and I have proved this by experiments made on our chambers and by observation of their temperatures. In our works we have two systems of chambers burning about equal quantities of pyrites. The first system consists of one set of five chambers with one Gay-Lussac tower, the second system of two sets of three chambers and two chambers respectively, both joining into a second Gay-Lussac tower. The nitrous liquor obtained from the Gay-Lussac tower is sufficient to supply the two small sets completely with nitre, and all necessary potting is done at the large system, which receives a very small quantity of nitrous liquor. Consequently the two small sets receive a continuous supply of nitrous gases and the large one a periodical one, although the potting is divided over as many intervals as possible. The two small sets show no variation of temperature except what is due to the variation of the surrounding air; the large set shows a very interesting variation, which is entirely due to the potting. This is done every two hours, and each time before potting, when the nitrous gases are lowest in amount in the first chamber, the temperature shows its lowest, rising slowly with the nitrous gas coming of the fresh pots. This variation extends from  $48^{\circ}$  to  $68^{\circ}\text{C}$ ., and repeats itself regularly, showing evidently that the temperature depends on the amount of nitre present, and as the temperature depends on the quantity of vitriol made, a fall of temperature indicates less vitriol made, owing to scarcity of nitre, provided the amount of oxygen is right, which will be shown by the test of the escaping gases after the Gay-Lussac tower. The thermometers were inserted 22ft. distant from the inlet of the gases at each set, and the gas entering it was about  $35^{\circ}\text{C}$ . in autumn and winter. The temperature of the small sets was from  $50^{\circ}$  to  $53^{\circ}\text{C}$ .

To prove further the influence of the quantity of nitrous gases present, I missed in an experiment the potting of nitre once at the large set, leaving the small quantity of nitrous liquor at the Glover tower untouched as well as the steam. The temperature fell to  $41^{\circ}\text{C}$ . The temperature of the entering gas was  $35^{\circ}$  in this case. The difference of  $6^{\circ}$  between  $35^{\circ}$  and  $41^{\circ}$ , is owing to the small quantity of vitriol made by the small quantity of nitrous liquor running down the Glover tower. The drips were—

	I.	II.	III.	IV.
Before starting.....	131	129	116	108
Lowest during experiment....	114	112	101	91

and large escape of sulphurous acid was observed at the Gay-Lussac tower. The chambers worked very irregularly after the experiment, until not only the missed nitre was put in, but an additional quantity of it, to compensate for reduction of the nitre, through excess of sulphurous acid on the small quantity of nitre present.

The quantity of nitre missed during experiment was 80 per cent. of the whole quantity entering per two hours. Another experiment with too much nitre was made at the small set, where no variation of temperature takes place. The temperature rose  $9^{\circ}$ , and the strength of vitriol increased from  $134^{\circ}$  to  $142^{\circ}$ , showing more vitriol was made. However, it is not advisable to work with a great excess of nitrous gas, on account of the losses increasing then by bad absorption at the Gay-Lussac tower, as shown previously. These experiments with nitre show the bad effect caused by shortness of it; and judging from the regular variation of temperature at the large system, it is certainly of advantage to have a continuous supply of nitrous gas entering the chamber to avoid reduction, which must take place to some extent when the nitrous gas is lowest in amount just before potting time. This is the reason the Continental works prefer using nitric acid.

Professor Lunge published experiments on the influence of steam on nitrous gas in *Dingler's Polytechnic Journal*, vol. 243. Mixing sulphurous acid, air, water, and nitric oxide above mercury there was always very considerable reduction to nitrous oxide, not to nitrogen. Mixing these gases above sulphuric acid of 1.455 specific gravity of  $14^{\circ}\text{C}$ ., no reduction took place. This shows considerable reduction takes place with excess of water and no sulphuric acid present; and this condition is fulfilled in the chambers at the inlet of the steam. In the first chamber generally acid of  $134^{\circ}$  is produced—that is, sulphuric anhydride with three equivalents of water. It is rather a hopeless task to find out by experiments on working chambers how much nitre is reduced by the three equivalents, because vitriol above  $134^{\circ}$  begins rapidly to destroy the lead of the chamber and to dissolve the nitrous gases. However, to find it out, I worked one set of chambers with four equivalents of water—that is, producing vitriol of about  $114^{\circ}$  instead of  $134^{\circ}$ . I chose for experiment one of the small sets, which receives a continuous supply of nitrous gas by nitrous vitriol. On account of this the temperature is very steady, and any change of it could be immediately observed. This set consists of three chambers, and during the experiment the vitriol produced in the two last chambers was kept the usual strength, everything else left the same as well. Each egg of nitrous liquor running down the Glover tower was tested for nitre to ascertain any variation of strength, which was of no consequence. The nitrous gas dissolved in the vitriol was equal to 1,852lb. of nitre in 96 hours, representing 8.7 per cent. of nitre on the quantity of sulphur charged (48 per cent. of pyrites). I have shown in the previous calculation, that an increase of one-third of steam, which is equal to the difference between  $114^{\circ}$  and  $134^{\circ}$ , could only increase the temperature by  $2.6^{\circ}$ , provided the same quantity of vitriol was made. The temperature before starting was  $50^{\circ}$ , and it rose at once to  $53^{\circ}$ , to remain constant for a few hours, when it began to fall slowly to  $46^{\circ}$ , which fall took 48 hours. Nitre had to be introduced, which rose the temperature to  $54^{\circ}$ ; the same slow fall of temperature repeated itself within the next 48 hours, when again nitre had to be potted. After 96 hours' duration the steam was put to its former standard,

and the extra nitre used weighed 60lb. For this set 1,852lb. were used during the 96 hours, consequently the 60lb. represent a reduction of 3·2 per cent. of this quantity, and 10½ per cent. of the lost nitre, using 2·75 per cent. The set worked very regularly during the experiment, and the reduction which took place was very gradual. According to this, 10½ per cent. of the nitre was reduced, producing vitriol with four equivalents of water in the first chamber. As reduction only takes place at inlets, as proved by the already-mentioned experiments of Professor Lunge, in *Dingler's Polyt. Journal*, the same amount must be reduced for the first three equivalents, being therefore 31·5 per cent. of the lost nitre.

There has always been much difference of opinion as to with what amount of oxygen the chambers ought to be worked. Dr. Hurter finds in his paper, published in the *Journal of the Society of Chemical Industry*, 1883, 6 to 10 per cent., according to working conditions. It depends, in my opinion, greatly on the available chamber space. I had opportunity to work chambers with different chamber space, and I found the results shown in this table could always be obtained, and remain within 0·5 per cent. loss of sulphur at the Gay-Lussac tower.

Chamber space.	Oxygen. Percent.	Nitre per cent. on Sulphur.
1' .....	4½ to 5	4'
1½ .....	5 5½	3·7
1½ .....	5½ 6	3·5
1½ .....	6 6½	3·1
1½ .....	6½ 7	2·8

If I tried to work the chambers much higher in oxygen, as represented in this table, sulphurous acid was carried away mechanically at the Gay-Lussac tower, and increased the loss of sulphur considerably, sometimes to about 2 or 3 per cent. Great excess of oxygen shows its effect at once at the temperature of the first chamber, which when it reaches over 10 volumes per cent. goes down to nothing much above the temperature of entering gases.

If the oxygen goes below 3 per cent. a great quantity of extra nitre must be used, which amounts in my experience up to 6 or 7 per cent. on the sulphur burnt. In this case a great amount of nitric oxide escapes at the Gay-Lussac tower, which then does not require any testing, but will show itself by red fumes at the outlet of the chimney, caused by the oxidation of the monoxide to nitrous anhydride, which reaction ought to have taken place in the chambers. This will explain the disadvantage of a small chamber space. In a small chamber space most of the vitriol must be made in the first part of it. In order to do this the circulating nitre per quantity of sulphur must be increased, likewise the chambers must be worked with less speed, which means less oxygen. Then the disadvantage of working with more circulating nitre is increased through shortness of oxygen, the greater quantity of nitric oxide is mixed with a smaller quantity of oxygen, therefore not oxidised so readily, and particles of it are more likely to be reduced by sulphurous acid to nitrous oxide. Besides this there is much less time given for its oxidation; proof of this that even with 1·47 of chamber space, still 7 per cent. of nitric oxide escaped unoxidised from the Gay-Lussac tower in the presence of 7 per cent. of oxygen. Working with large chamber space less vitriol is required to be made in the first chamber, the formation of it being divided over a larger space; the chambers can be worked with less circulating nitre and with more oxygen; and more oxygen being present for a smaller quantity of nitre, the monoxide is more readily oxidised and likewise allowed more time for

its oxidation. In our works the 2·75 per cent. of nitre used divides itself as follows—

Gay-Lussac tower .....	0·330 or 12	as soluble nitrous gases
Gay-Lussac tower .....	0·192 or 7	as nitric oxide
Glover tower, leakage, etc. ...	0·082 or 3	
	0·866 or 31½	from steam at inlets
	1·470 or 53½	accounted for

This leaves 46 per cent unaccounted for, which is due to the insufficient chamber space, to the irregularity of introducing the nitre, and to inevitable accidents, which are all included in the 2·75 per cent.

Before concluding this paper I should like to say which will be the lowest quantity of nitre by which vitriol could possibly be made. To this purpose would be required a chamber space of about 1·8 or 2 cubic metres per kilo. of sulphur, a regular stream of nitrons gases entering the chambers, strength of vitriol and oxygen kept right, and a sufficiently large Gay-Lussac tower, to allow no more than 0·33 per cent. of the soluble nitrous gases to escape. The losses would then divide themselves as follows :—

Gay-Lussac tower .....	0·330 = 26
Glover tower, etc. ....	0·082 = 6
Steam at Inlets .....	0·866 = 68
	1·278 = 100

making no allowance for inevitable irregularities.

#### DISCUSSION.

Dr. HURTER said the paper was an exceedingly interesting one. Many years ago another of Messrs. Muspratt's chemists, Mr. Vorster, made investigations into the losses of nitrate occurring in the manufacture of vitriol, and the results arrived at by Mr. Vorster bore out Dr. Eschellmann's remarks as to the very large amount of nitrate put into the system which could not be accounted for. Mr. Vorster came to the conclusion that the main loss occurred in the Glover tower. Shortly after Mr. Vorster's paper appeared the Noxious Vapours Manufacturers Committee commenced its operations, and he (Dr. Hurter) made a number of experiments very similar to Mr. Vorster's, from which he arrived at a similar conclusion, viz., that the denitration of nitrous vitriol could not be carried out without loss. On the other hand, Professor Lunge now maintained that the whole of the nitrate was probably lost in the Gay-Lussac tower. Professor Lunge, in the paper to which Dr. Eschellmann had alluded to, said that with a proper construction of chambers and skilled working, but only under these conditions, the chemical losses unaccounted for were, if not absolutely zero, far too small to be taken into consideration; but this would not apply in works where more than 3 per cent. of nitrate was used. So that Professor Lunge's position now was, that where only 3 per cent. of nitrate was used the greater proportion of loss could be accounted for. Dr. Eschellmann had told them that all the loss accounted for by Dr. Lunge amounted to 50 per cent. of the total nitrate used. Looking at Professor Lunge's experiments more carefully, he (Dr. Hurter) found them to be such as could not be accepted as normal experiments. The amount of nitrate used must certainly have been more than that on which the loss had been calculated; and he objected to the experiments because the amount of nitrogen compounds escaping at the Gay-Lussac were abnormally large. Dr. Eschellmann's observations agreed entirely with what Mr. McTear, Mr. Jackson, and himself had published years ago, viz., that there was certainly somewhere in the system a loss of nitrogen compounds which could not be discovered by the methods of analysis at present at disposal. It was asserted in reply to this that their methods of analysis were bad, so that they

could not discover the amount of nitrate leaving at the Gay-Lussac. He agreed that they were had if they only showed 80 per cent. of the quantity passing away, but nevertheless this did not affect the general conclusion that there was a very large amount of nitrogen compounds lost. Dr. Eschellmann had endeavoured to show where the loss occurred; and had stated that the temperature of the chamber was an index to the amount of vitriol made in the chamber. He entirely agreed with Dr. Eschellmann in this, and he believed that the amount of steam introduced and the air outside had comparatively small influence upon the temperature. On the whole Dr. Eschellmann had shown a state of affairs very much the same as he himself and the other chemists he had named had found some time since. It was very important to find out where the loss took place; and supposing 31½ per cent. to be lost in the chambers, Dr. Eschellmann pointed to the fact that it was perfectly useless to attempt to find methods to work with a small chamber space, which meant working with a large amount of circulating nitrate; but he could not entirely agree with the method by means of which that loss in the chambers was established. The experiment had lasted only a short time, and the amount of nitrate potted was a small fraction of the whole nitrate in circulation, which, to his mind, rendered the conclusion doubtful.

Dr. HAMBURGER: The question of the consumption of nitre in O.V. chambers is as interesting as important to the manufacturer. I have myself made experiments on that subject, and my figures very closely agree with those of Dr. Eschellmann. The so-called mechanical loss, excluding NO, amounts in our works (Messrs. Gamble, St. Helens) to about 22 per cent., chamber-room and nitre consumption being nearly the same as stated by the lecturer. I also believe that the excess of water, or rather steam, in the chambers has a great deal to do with the reduction of N compounds to  $N_2O$ . I think it was R. Weber who first pointed out this as a possible source of loss ( $N_2O_3 + 2SO_2$  and  $2H_2O = N_2O + 2SO_4H_2$ ); but another loss, which might be very considerable, is the escape of NO and  $N_2O$ . I have failed in determining NO with permanganate, as suggested by Prof. Lunge. Samples drawn at the same time from two openings of the chamber escape tunnel, close to each other, gave different and therefore unreliable results. Another cause of loss was suggested by Mr. Davis, some years ago, as taking place in the Gay-Lussac tower by the oxidation of  $As_2O_3$  into  $As_2O_5$ . It was rightly observed at the time that this cannot be serious, as works making sulphuric acid from brimstone, and working with Glover and Gay-Lussac towers, do not experience this loss; they should, consequently, show a great reduction of their nitre consumption, which is not borne out in practice. I am not satisfied with the explanation given by certain investigators, who think they can account for nearly all the nitre lost in the manufacture of O.V., but am rather of opinion that there is something going on within the chambers of which we at present know nothing, and which causes the reduction of nitrogen compounds into such which we cannot recover. In conclusion, I wish to say that the principal points for a low nitre consumption are increased chamber space, a small amount of circulating nitre combined with sufficient absorption plant, and, as Dr. Eschellmann showed, regularity in the supply of nitre. With regard to "chemical loss," I quite endorse the words of Mr. Maetear (*Chem. News*, 1879, page 232): "The unaccounted-for loss is intimately connected with the working of chambers, as in most cases it is found that where the percentage of nitre used on sulphur is high, so also is the loss of nitre unaccounted for calculated on sulphur."

## REPLY.

Dr. ESCHELLMANN, in replying, thanked the meeting for the kind attention given to his paper. He was much pleased that Dr. Hurter's experiments agreed with his own.

The CHAIRMAN said they were much indebted to Dr. Eschellmann for his paper, which had been a very interesting one, and had cleared up some doubtful points in the sulphuric acid manufacture. The discussion on the question had been going on for some time, having been started by some experiments made by Mr. Vorster at the works with which he (the chairman) was connected. Undoubtedly some of Mr. Vorster's conclusions were wrong. He based his calculations too much upon experiments in the laboratory rather than in the chambers themselves. As to Professor Lunge, it was evident that he had worked with an excess of nitrate. A number of experiments had been made by the Committee of the Alkali Manufacturers' Association at ten works, and from calculations he had made—assuming, which he did not think would be far wrong, that the average amount of nitrate used in those experiments was 4 per cent.—he found the total escape in grains of nitrogen per cubic foot would represent somewhere about 20 per cent. of the total loss, owing to the non-absorption in the Gay-Lussac tower.

---

## ON THE ACTION OF NITRATES ON ALKALINE SULPHIDES.

BY E. W. PARNELL.

IN the spring of 1882 I read a paper before this Section of our Society, giving an account of some experiments I had made on the action of nitrates on alkaline sulphides at different temperatures in an alkaline solution, the object being more especially to investigate the formation of ammonia, which different authorities had represented to be produced from the nitrate at certain stages of its reduction. From my experiments I ascertained in the first place that the proportion of ammonia evolved during the oxidation of crude Leblanc liquors is very far below what would be produced if the action that takes place had been correctly represented by the authorities above referred to; and secondly, that when especially prepared solutions are employed, in the place of the crude Leblanc liquor, oxidation of the sulphide goes on without any formation of ammonia whatever. From this I assumed that the ammonia evolved from the Leblanc liquors arose from the decomposition of cyanides, but remarked that the subject called for further investigation. Since then the matter has been further investigated by Professor Lunge and Mr. J. H. Smith, an account of an elaborate series of experiments having been published by them in the numbers of our Journal for November and December last. In these experiments the authors follow closely the action of the nitrate through its various stages, and investigate in an exhaustive way the gradual oxidation of the sulphur compounds under greatly-varying conditions. The conclusions at which they arrive with regard to the formation of ammonia, and to which I wish now especially to draw attention, are, first, that when the action takes place on the large scale in the manufacture of caustic soda by the Leblanc process, ammonia is produced from the nitrate by the reducing action of the metallic iron of the vessels in which the operation is conducted; secondly, that a small proportion of nitrate is reduced to ammonia by the action of the sulphide, in absence of iron; and thirdly, that when metallic iron is present the action of the

nitrate on the sulphide is hastened by the action going on between the iron and the nitrate. The figures that the authors give in these two cases are, in absence of iron, of the total nitrate decomposed by the sulphide, 1·4 per cent. is reduced to ammonia; while when metallic iron is present the proportion rises to 10·4 per cent. It will be seen, therefore, that in the former case the authors practically confirm what I had pointed out, namely that the formulæ given by earlier authorities, in which ammonia was represented as being produced to a considerable extent, are incorrect. The conclusions, however, at which they arrive with regard to the part played by the metallic iron cannot in any way be reconciled with some of the results obtained in the experiments I had made. In criticising these results the authors dispose of the differences by simply assuming that my experiments must be "wrong." Now in any case such a conclusion is a very unsatisfactory one. I, knowing the care with which my former experiments had been conducted, might with equal reason assume that the authors' experiments were wrong. I thought it better, however, to investigate further, and, if possible, to discover the cause of the apparent discrepancies, and I now propose to give an account of the results of some experiments I have made with this object. In the first place, the authors speak of the reduction of nitrate by metallic iron in an alkaline solution as if it were a simple matter, and refer to a well-known method of estimating nitrate based on this reaction. Now the only analytical method that I can think of to which they refer is that known as Harcourt and Stewart's, where zinc and iron filings are employed together. In this case, however, even if the iron were able to act alone, any such action would be entirely prevented by the zinc, which at once throws the iron into an electro-negative condition. In this method the use of the iron filings is simply to hasten the solution of the zinc by galvanic action. The authors further say that they have succeeded in reducing as much as 90 per cent. of nitrate to ammonia in an alkaline solution by means of metallic iron. This is to me most extraordinary, as although I have made repeated trials with different proportions of materials and varying strengths of solution, I have in no case been able to get any satisfactory addition of the nitrate. I have found that generally on commencing to boil, ammonia to a slight extent has been produced, but that the action quickly ceases, no more ammonia being evolved until a temperature of 450° to 500° Fahr. is reached, when a further slight reduction takes place. My experiments were as follows: I first boiled a solution containing 50grms. of white fused caustic soda of high strength, and 2grms. of potassium nitrate, with 5grms. of very fine iron wire, in a flask connected with a suitable condensing apparatus. The connecting tube was about  $\frac{3}{8}$  in. internal diameter, and for a length of about 18 in. had a fall towards the flask, so that liquid condensed in it might be returned to the boiling mixture. The object of this was to entirely free the steam from the minute particles of alkali that are always carried away from a boiling caustic solution. On commencing to boil the volume of the solution was about 100c.c. In twenty minutes 42c.c. had been carried over, and the ammonia condensed was only 0·0003grm.  $\text{NH}_3$ . A similar experiment with the same quantities of iron and nitrate gave 0·0006grm.  $\text{NH}_3$ , after twenty-five minutes' boiling. Iron filings give rather better results. 5grms. in a solution of 50grms. of caustic and 2grms. nitrate gave 0·006grm.  $\text{NH}_3$  by the time a temperature of 450° Fahr. had been reached in the decomposing flask, while in another case 0·009grm.  $\text{NH}_3$  by boiling up to 560° Fahr. Even this, however,

only represented 3 per cent. of the nitrate reduced to ammonia. If zinc be added a very different result is obtained, as the following experiment shows: 50grms. of caustic, 2grms. of nitrate, and 5grms. of iron wire, in about 120c.c. of water, were boiled for half an hour, and gave 0·0007grm.  $\text{NH}_3$ . The liquid in the flask was then diluted to its original volume, and 3grms. of zinc were added. Boiling then for thirteen minutes gave 0·1grm.  $\text{NH}_3$ , about 140 times as much as had been produced by the previous half-hour's boiling. Now, on referring to Lunge and Smith's paper, and to their experiments on this subject, at page 461 of the number of the Journal for November last, it will be seen that they employ a caustic solution that yields ammonia on being boiled alone, as before adding iron wire they say they boiled 150c.c. of 90° Tw. liquor for half an hour, and "estimated the ammonia." If they employed crude liquor, sulphide would also be present. How they can therefore, from operations on such a mixture, conclude that their "experiments re-establish the generally well-known fact that iron does reduce nitrate to the form of ammonia in a boiling caustic solution" is more than I can understand. In the first place, the evolution of ammonia from boiling Leblanc liquors does not cease, at all events, at 570° Fahr., as the following experiment shows: 100c.c. of crude Leblanc liquor of 90° Tw. were boiled, and the ammonia collected, with the following results:—

Time. Minutes.	Temperature. F.	Total. $\text{NH}_3$ . Grms.
8	360°	·0006
17	462°	·0102
20	526°	·0137
21	540°	·0165
21½	550°	·0179
22½	570°	·0190

It is quite possible that this evolution may be modified under the changed condition of their experiments. So far, therefore, the difference to which I had previously called attention between the action of nitrate on pure sulphide in a pure alkaline solution, in which case no ammonia is produced, and the corresponding action in Leblanc liquors, cannot be accounted for by the action on the metallic iron. In order to discover the cause of this difference I next proceeded to add to the mixtures, as before prepared, small quantities of the different impurities found in Leblanc liquors. Without going into unnecessary details, the result was that I found that the addition of a very small proportion of iron oxide caused the formation of a large proportion of ammonia—that, in fact, the formation of ammonia is simply due to the action of nitrate on ferrous sulphide, which is oxidised to ferric oxide, and then reduced by the alkaline sulphide to ferrous sulphide again, this action and reaction continuing until one of the reagents is exhausted. In ordinary Leblanc liquors the proportion of iron held in suspension or solution is not sufficiently large to cause much of the nitrate to be reduced to ammonia in this way, but a very small addition of an iron salt increases the proportion enormously. It is strange that this action and reaction should have entirely escaped the notice of Lunge and Smith, as they actually speak of the oxidation of ferrous sulphide by the nitrate, with formation of ammonia, as one of the *probable* stages of the oxidation of the iron. But it seems never to have occurred to them that the ferric oxide would at once be reconverted to ferrous sulphide by the action of the alkaline sulphide. The action on the ferrous sulphide begins at a much lower temperature than the corresponding action on pure alkaline sulphide, although it is very feeble under about 370° Fahr. This action and reaction, however, together with the fact of any oxidation of ferrous sulphide going on at less than 370°

Fahr., is quite sufficient to explain the differences between the results of Lunge and Smith's experiments and those of my former ones; and which differences they expressed themselves unable to account for. In criticising my results they seem entirely to have overlooked the fact that I operated on especially prepared pure solutions, and also that in my former paper I had myself especially drawn attention to the difference between the behaviour of such mixtures and Leblanc liquors on the large scale.

I give here a few experiments on the action of the iron sulphide. A solution of caustic soda of 90° Tw. was prepared from pure caustic, and pure sulphide added equivalent to about 2 parts of Na<sub>2</sub>S to 100 parts Na<sub>2</sub>O; 100c.c. were boiled with addition of nitrate up to 550° Fahr., when all sulphide had disappeared and no ammonia had been produced; 100c.c. were next taken, and 1·5grm. nitrate and 1grm. ferrous sulphate added: ammonia appeared at 280° Fahr., was rapidly evolved at 370° F., and ceased at about 500° F.; the proportion corresponding to about 88 per cent. of the nitrate employed. In this experiment the nitrate was insufficient thoroughly to oxidise the sulphide. 100c.c. were taken and boiled with 1·5grm. nitrate and 2grms. ferrous sulphate. The proportion of ammonia was not increased, however, and in no case could more than 90 per cent. of the nitrate be reduced to ammonia. In the experiment where 1grm. of ferrous sulphate was employed, the ammonia due to its oxidation amounts to 0·007grm. NH<sub>3</sub>, while the total NH<sub>3</sub> obtained was 0·22grm., thus showing that the iron had acted and reacted some thirty times. In another experiment I operated with a much smaller proportion of ferrous sulphate—0·05grm. to 2·5grms. of nitrate, the latter being slightly in excess of the sulphide. In this case the ammonia obtained amounted to 0·09grm.; that due to the action on the ferrous sulphide was only 0·0003grm., so that the latter had done its work some three hundred times. Ferrous oxide alone in absence of sulphide reduces nitrate to ammonia in a boiling alkaline solution, and in some cases I have succeeded in obtaining very nearly the full amount corresponding to the formula

2grms. of ferrous sulphate, for instance, boiled with ½grm. nitrate and 50grms. caustic, gave 0·0162grms. NH<sub>3</sub> against 0·0152grm. calculated. I find that zinc oxide acts in a similar way to the iron oxide, but not by any means so rapidly. Caustic soda made from liquors that have been freed from sulphide by means of zinc frequently contain a small proportion of the latter, and in one of my experiments I obtained ammonia in absence of iron, which I subsequently ascertained to be entirely due to this. Caustic soda solutions of 90° Tw. will hold up zinc in presence of sulphide, so that in such a case the presence of the zinc may easily escape one's notice.

The conclusions at which I arrive from these and my former experiments therefore are: (1) That oxidation of alkaline sulphide by nitrate in a boiling alkaline solution does not commence below 370° F.; (2) that oxidation takes place without formation of ammonia; (3) that ferrous sulphide, ferrous oxide, zinc sulphide, and no doubt some other metallic sulphides are oxidised by nitrate, in a boiling alkaline solution, with formation of ammonia, and that consequently when any of these, more especially the iron compounds, are present in a mixture of caustic soda, nitrate, and alkaline sulphide, ammonia to a large extent may be produced on boiling; and (4) that metallic iron has a very feeble reducing action on nitrate, with formation of ammonia in a boiling alkaline solution. Now, on referring to the paper of Lunge and Smith, it will be seen that all

apparent discrepancies can easily be explained. They boil the iron wire in a solution containing sulphide. The latter attacks the iron, in this case no doubt producing ammonia from the simple action itself, but by increasing the proportion of iron sulphide in suspension or solution in the mixture, they enormously increase the amount of ammonia obtained when alkaline sulphide is being oxidised by nitrate. Iron is always present to a certain extent in crude Leblanc liquors, consequently as they only experimented on crude liquors they invariably obtained some ammonia. The discrepancy between one experiment of mine and theirs, to which they draw especial attention at page 461, and to which I have already referred, where I found an addition of iron caused no increase of ammonia, is explained by the liquor containing only a very small proportion of sulphide, 0·12 to 100 of alkali, as shown in the analysis. I have therefore no modification to make in any of the direct conclusions I drew from my former experiments, the object of which was as much to investigate the purely abstract question of the action of the nitrate on the sulphide as the actions that go on in the Leblanc liquors. Of the latter I remarked that "by adding a by no means excessive quantity of nitre to the boiling liquid before it reaches 90° Tw., it is possible greatly to reduce the proportion of sulphide, and that under these circumstances sulphite and not sulphate is principally formed. Further, that it is well known that at certain stages of the boiling an addition of nitre is immediately followed by an unmistakable evolution of ammonia." I said that I was "only able at the time to suggest an explanation of these differences, and that is that some cyanogen compound, possibly the sulpho-cyanide, acts as a carrier of oxygen from the nitrate to the sulphide, the cyanogen at the same time being partially split up." What I have, therefore, to modify in my former paper is the negative conclusion, or rather assumption, that all the ammonia was derived from the cyanide in the case of Leblanc liquors.

## ON THE DYEING PROPERTIES OF ANTHRACALLOL.

BY DR. R. BOURCART.

I WILL endeavour to show you this evening illustrations of cloth mordanted with iron and alumina and dyed in anthracallol. This substance has been known for several years, and was discovered by Säuberlich, but it has never been pointed out that it is a

colouring matter. About three years ago Mr. von Georgievics and myself made some experiments on anthragallol, and we prepared several amido compounds of this substance, which formed the subject of a note which Professor Noelting presented to the Société Industrielle de Mulhouse. We did not communicate our discovery about the dyeing properties of anthragallol because at that time alizarin was more expensive than it is now, and there was some hope that it might be useful as a substitute for that colouring matter. Since last year, however, the price of alizarin has fallen very much, owing to the patents which have been taken out for its manufacture having expired, and the difference between the prices of alizarin and anthragallol is accordingly too great at present to permit any hope of the latter being used as a substitute for the former unless somebody finds a way of increasing the yield of manufacture or a means of lowering the cost of substances used in the preparation of this dyestuff. I have the honour to show you two bottles containing anthragallol in a suspended state similar to that in which alizarin is sold. Both bottles contain the same substance prepared by two different methods. The first illustration is the result of the combination between benzoic acid and gallic acid in the presence of sulphuric acid. This combination should rather be called a cementing together of two organic nuclei of benzol. Two molecules of water are eliminated and the well-known double nucleus of anthracene is formed, so we see that anthragallol and alizarin are derived from the same hydrocarbon, which is anthracene. In the case of alizarin, we take anthracene and modify it slightly so as to change it into alizarin, but in the condensation referred to we make anthracene, or at least one of its derivatives, which is anthragallol. The latter could, if required, be easily converted into alizarin or anthracene through chemical reactions so as to prove its construction. My other illustration is prepared in the same manner as the first, only here the substances which combine are phthalic acid and pyrogallol. In both cases, after treating for several hours with an excess of sulphuric acid and letting it cool well, the dyestuff is precipitated by pouring the sulphuric solution into a great quantity of water and washing on a cloth-filter till there is no acid present. Anthragallol contains one atom of oxygen more than alizarin. It is an isomer of purpurin, having the same composition and containing the same percentage of the various elements, carbon, hydrogen, and oxygen as purpurin; but those atoms are placed in a slightly different

Illustration of dyed Anthragallol: Light brown, mordanted with pure alumina; dark brown, with alumina and iron; light and dark drab, with iron.

position in the molecule. Purpurin is one of the colouring matters from madder. It gives red lakes with alumina and purple lakes with iron. Anthra-

gallol gives brown lakes with alumina and black lakes with iron, is perfectly fast to soap, and withstands strong bleaching liquor the same as alizarin colours will do. I have tried to prepare anthragallol in a third manner by starting from nitro-alizarin, and although I have obtained substances presenting great interest from a scientific point of view, I have not been able to transform them into anthragallol. I have now the honour of showing you illustrations of printed cretonnes from Alsace. The large ones have been kindly lent to me by Professor Roscoe. They are from Thierry-Mieg, in Mulhouse. I have also a selection of very fine cretonnes mostly from Weiss-Fries, in Mulhouse. These cretonnes are done partly with machine and partly with block, and some of them first with machine, and then fitted in with block. I draw your attention to those furnitures, two yards wide, done entirely with block. I have also a very fine selection of prints from Switzerland, presented to me by four firms in Glarus. Some of the veils are calendered together four pieces thick, and printed four together with block. They are done with aniline colours, mostly for the Oriental markets. Here are also handkerchiefs, sold in the Oriental markets for head-gear. They are nearly all black, this colour being in great favour amongst the Orientals, and are ornamented round the border with fine aniline colours. Here is also a splendid selection of Swiss turkey-red handkerchiefs, from the works of Colonel Tschudi, in Glarus.

#### NOTES ON SOME OF THE MODES OF PREPARING, BLEACHING, DYEING, AND FINISHING COTTON GOODS, PRACTISED BY LANCASHIRE AND YORKSHIRE DYERS, AND THEIR RESULTS.

BY JAMES SHARP.

IN accepting the kind invitation given me through your worthy chairman, Mr. Ivan Levinstein, to read before you a paper on dyeing, I did not lose sight of the fact that the Manchester Section of the Society of Chemical Industry numbers amongst its members men whose intelligence, combined with the practical knowledge acquired during a long and varied experience in every branch of bleaching, dyeing, and finishing cotton goods, has won for the productions of Lancashire, generally known as Manchester goods, a position in the markets of the world unsurpassed, if even equalled, by that of the productions of any other country. Having thus the great advantage of addressing my remarks to men thoroughly acquainted with these important branches of textile industry, I chose as the subject of this evening's paper that branch in which you are most especially interested, and in which you have had a life-long experience, rather than the special branches of dyeing and finishing mixed goods, which would have afforded me greater scope for comment and illustration; for there can be no doubt, according to my opinion, that the preparing, mordanting, dyeing, and finishing of all the various kinds of mixed goods known as Bradford stuffs, requires a much more extended experience than is needed for the successful treatment of other goods. For many years large quantities of cotton goods have been sent by Manchester merchants to Yorkshire dyers to be dyed and finished, and as a matter of fact the Lancashire and Yorkshire methods of preparing, dyeing, and finishing cotton goods, as well as the machinery employed in

the two localities, are different one from the other, and the results produced are quite distinct. It is to the comparison of these methods, and the results obtained by them, that I invite your attention this evening. In order to bring before you more clearly some of the different methods of treating cotton when mixed with worsted, I shall also have to make some remarks on Bradford stuffs, and shall submit to you some dyed effects in which the worsted has been dyed one colour and the cotton another; but the intention of this will be mainly to show you that in bleaching, mordanting, and dyeing the cotton warp of mixed goods we cannot avail ourselves of the Manchester methods, inasmuch as it is necessary to have a complete control of the application of the dyeing materials.

Before commencing my remarks on dyeing I ought perhaps to say that I consider that the machinery and apparatus employed in Lancashire, such as washers, kiers, scutchers, jigs, pads, mangles, calenders, beetles, and, in short, all other appliances

dyers, and finishers cannot in many respects be surpassed, and having already referred to the high estimation in which the machinery and apparatus of Lancashire are held, I think it only right to admit the fact that on the introduction of the mixed goods known as Bradford stuffs, when no cotton-dyeing appliances existed in Yorkshire, both the Yorkshire dyers and machinists were very much indebted to the great progress which Lancashire had made in the production and application of machinery for dyeing cotton goods, inasmuch as such machinery was applicable to the dyeing, though not to the finishing, of Bradford stuffs. Indeed, some of your machinery was so perfect more than thirty-five years ago, that although many working improvements have since been introduced the principle remains unaltered.

I well recollect the first cotton-dyeing machine that came into Yorkshire—it was a padding machine, supplied by a Manchester firm. At that time the workmen took a keen interest in the introduction of machinery, and on seeing that by this machine goods

FRONT ELEVATION

TREBLE CRABBING MACHINE WITH PATENT STEAMERS.

used in bleaching, dyeing, and finishing cotton goods, have attained a very high pitch of perfection, and are admirably calculated to produce the results which more especially characterise Manchester goods. The great demand for these goods is the best proof of the high estimation in which they are held by the public. I mention this more particularly because I shall show that in Yorkshire the machinery and mode of treatment differ entirely in several important particulars from those in use in Lancashire, and therefore any special aptitude which the Yorkshire dyers have acquired in the dyeing and finishing of cotton goods, and more particularly in that class known as "Italian cloths," is principally owing to the application of principles distinct from those in use in the Lancashire trade and to the use of machinery capable of producing different results. I do not pretend that the standard of skill amongst the Yorkshire workmen is higher than is the case in Lancashire. An examination of the goods in the Manchester warehouses will furnish abundant proof that the Lancashire bleachers,

could be so quickly tinted in various shades by simple padding, as it is termed, they named it the galvanising machine. A few months afterwards your dyeing jiggers were first introduced into the Yorkshire dye-houses, and became rapidly adopted throughout the trade. Some years later, viz., in 1852, I became head dyer at the works where the above machinery was first introduced, and for some years after I dyed large quantities of goods with the same machinery. Since that time nearly the whole of the Lancashire cotton-dyeing machinery has been adapted and altered to meet the special requirements of the Bradford trade, by giving to it increased size, increased strength, and additional parts, with the object of making it suitable for dyeing equally with either mixed goods or all-cotton goods in much larger quantities than can be dyed with machinery employed in the dye-houses throughout Lancashire. But what I have to bring before you more particularly is the use of machinery and processes distinct from those employed in Lancashire. Therefore, I propose to show that by treat-

ing cotton Italian cloths on worsted machinery, the same as if they were worsted (or real) Italians, whether in the processes of preparing, mordanting, dyeing, or finishing, the result is that we approach much nearer to the characteristic finish which especially belongs to the real or worsted Italians than it is possible to arrive at by the modes of treatment generally adopted in the Lancashire dye-houses. The Yorkshire mode of treatment which I am now going to bring before you is more especially applicable to the dyeing and finishing of black and dark-coloured goods. This fact, I believe, has for years been fully admitted both by dyers and merchants in Lancashire, and the result is that the black cotton Italian dyeing has to a very large extent been done in Yorkshire. Although for several years the prices paid for this work were more than double the price paid to-day, no Lancashire dyer took up this branch of the trade, and the present unremunerative prices are owing

Halifax, I am able to place before you drawings of some of their machinery, with all the improvements, some of which are a great advance on the original machine. Simple as this crabbing machine may appear, it is by the skilful use of it in preparing, or as we term it, "gray-finishing," all the various kinds of goods, that we increase the length by two or three yards per piece, produce the gloss or lustre on alpaca goods, give the smooth, close silky finish to Italian cloths or other goods, also impart the soft cloth-handle to all-wool goods and cashmeres, and, what is more important, the finish put upon the goods by this machine is permanent, and withstands the action of the boiling dye-vat. The drawing before you represents a treble crabbing machine, each crab having separate motion or gearing. Practically these crabs are identical one with the other, and each crab has nine parts, used to produce the various finishes. These are marked alphabetically in the order in which they are

PADDING MACHINE.

principally to the competition amongst the Yorkshire dyers during the somewhat depressed state of the Bradford trade. The result has been to make the dyeing of cotton goods equally unprofitable with that of Bradford stuff. You may have heard something lately about the advance in prices, of which I will only say that it does not more than cover the increased length and weight of the goods. The prices hitherto ruling had been so low that the invention of both dye and machine makers, as well as the improvements made by the dyer, had failed to make them remunerative.

I will now invite your attention to the drawings representing a treble crabbing machine, which is not used in the Lancashire dye-houses, but is indispensable in the finishing of worsted and mixed goods, and which, as I hope to be able to show you, has some advantages in the finishing of cotton goods. By the courtesy of Messrs. Elkana Hoyle and Sons Limited,

used. A is the beaming or batching roller, B is the brake to put tension on the cloth, C is the trough for boiling alkaline solution, D is the roller in the trough to give increased tension, E is the iron squeezing or crab roller, F is the rack for raising or lowering the top roller, G the lever for putting pressure on the top roller, H the expanding roller to prevent creasing, and I the taking-out or rolling motion. To begin with, the workman causes about five pieces of worsted or cotton Italians to be stitched in one length, with wrappers to protect the outer ends. You will notice that I am passing over the preliminary process of stamping or marking, also of stitching and singeing the goods, as the slight variations in the practice of the different firms do not affect the results which I am desirous of bringing before you. The batch of goods is taken from the singeing and laid in open fold, convenient for being wrapped or batched round the beaming roller A. This only places the goods in a convenient position

for treatment on the first crab. The trough C is made ready with boiling alkaline solution, when the wrapper which is stitched to the end of the goods is threaded, in open width, through the boiling water under the small roller D, then wrapped round the bottom crab roller E, as shown in the drawing. The brake B is adjusted to give the proper tension to the goods, and the top crab roller E, which has hitherto been raised, is now lowered to bear upon the cloth, and when necessary additional pressure is put upon the cloth by the lever G. The crab is put in motion, and under these conditions the cloth is drawn or made to travel from the beaming roll A through the boiling alkaline solution on to the bottom crab roller E. This process is repeated upon the goods as they are made to travel in like manner to the second and third crabs, after which they are taken on to rollers by the taking-out motion I. The expanding roller E, as already mentioned, is for the purpose of keeping the goods free from creases during the process of batching on to rollers. Worsted goods require to undergo other processes which are not necessary in the case of cotton goods. The steam-

*Side Elevation.*

YORKSHIRE JIGGER.

ing and reversing appliances attached to the crab, and marked J, are only applicable to the finishing of Bradford stuffs, and are the patent rights of Messrs. Elkana Hoyle and Sons, Halifax. This crabbing machine is capable of preparing about 20 pieces per hour, or 200 pieces per day of 10 working hours. I will now submit to you two samples of worsted Italians. The one which is so rough and shrivelled has been dyed without having been crabbed in the way I have described, and affords a practical proof that goods so treated would be completely spoiled. The other pattern, which has a smooth, close, lustrous appearance, and a glove-like handle, has been crabbed previous to being dyed, and this very considerable difference in the result is due to the process of crabbing which I have just explained. Now after placing before you proofs of the remarkable effects produced upon worsted or real Italians by the process of crabbing, I have to point out to you one other result, viz., that in treating cotton Italians with the crab in the same manner as real Italians we obtain an increased length, a smooth, close, even, surface, a softer or more cloth-like handle, and the condition of the goods is not only most suitable for dyeing black, but, what is of very great importance, the weight of the cloth is fully 10 per cent. heavier than that of similar goods which are

prepared by kier bleaching. It may possibly be said that goods are not always kier bleached for black, but as some works do adopt that system I will deal with it in due course. For the present I would just call your attention to the sizing of cotton warps, a process which, as you well know, materially increases the weight of the warp, and it is not necessary for me to tell you that the warp only is subjected to this process before it is woven into the piece. The size being a glutinous body stiffens the threads by coating and filling the capillary tubes of the fibres, thereby making the warp stronger and better to work in dressing and weaving. It also gives a stouter handle to the cloth; and I think I may go so far as to say that the sizing of warps is indispensably necessary, and is not done for the purpose of fraud, whilst the cotton yarn used as weft, and which in weaving is made to form the face of the piece, is kept as light and lofty as possible, because in that condition it gives to the goods a kinder or more cloth-like handle. Now the object of the Yorkshire dyer is to maintain these conditions as far as possible, and we are of opinion that the process of crabbing is best calculated to maintain the original

*Side Elevation*

LANCASHIRE JIGGER.

weight of the goods, and to produce increased length and improved handle.

You will now allow me to say a few words on two customs which are prevalent in at least some of the Lancashire dyehouses. One is that when goods are for common black, the dyer receives them direct from the singeing operation, in which case they undergo no preparation equivalent to crabbing. In this case you maintain the weight of the cloth without obtaining any of the other advantages of the process of crabbing. The other is that of treating all goods by the well-known processes belonging to kier-bleaching, quite irrespective of whether they are for white, black, or colours. They are kier-boiled in strong alkali, often under pressure, and subsequently treated with strong acid, then again with bleaching liquid, and afterwards with acids. Now, whilst these processes, which effect a thorough bleaching of the cloth, are quite indispensable when the goods are for white or delicate colours, what are the effects which this severe chemical treatment has produced upon the cloth? It has not merely removed foreign substances, which is necessary in order to produce a pure white, and at the same time made the goods lighter and thinner, but it has also deteriorated the quality of the materials of which the goods are made, and left the latter in a

most unfavourable condition for dyeing a good black.

This brings us to the process of mordanting the goods, and I propose first to explain the processes of mordanting and dyeing as practised in Yorkshire, and in so doing I have to invite your attention to the drawings of two jiggers. The smaller one represents the most improved jigger as used in the Lancashire dyehouses, and as far as regards size it is the same as was first used in Yorkshire. The larger drawing represents the largest size used in Yorkshire dyehouses. A batch or charge for the small jigger is generally 5 pieces of 75yds. each, whilst a batch or charge for the large jigger, as worked in Yorkshire, is 40 pieces of 75yds. each, so that in preparing 40 pieces you employ here 8 jiggers with 4 men, whilst in Yorkshire 40 pieces are prepared on one large jigger with two men to attend to it. I must now direct your attention to the goods, which, after having been crabbed in the very way described, are brought on to these large jiggers, and the first process is to sumac or impregnate the cloth with any of the substances usually employed which are richest in tannin,

dye-bath they are a red shade of black, which is afterwards corrected to the proper shade in various ways, and by the use of a variety of materials. In Lancashire I believe soluble oil is one of the articles much in favour, but it is the method and the result that I have to deal with rather than the dyestuffs and materials employed, inasmuch as results equally good can be attained by the use of very different materials. Therefore, whether you bottom your goods with cutch, sumac, divi-divi, myrabolams, iron salts, copper salts, or by a judicious mixture of some of these, good blacks can be produced, but the comparison I want to bring before you is this, that whilst in Lancashire the processes of preparing and dyeing black are generally done on small jiggers, where the dye is not fixed boiling hot, in Yorkshire the goods are dyed in the large vats represented in the drawings, and in the way which I have described, after which they pass through the usual processes to condition them for finishing, and I believe you are aware that in Yorkshire these goods are finished by hot pressing. This process enables the workman to produce a watered effect on the back and a satin finish

FRONT AND END ELEVATION OF SILK COMPARTMENT BLACKING MACHINE.

after which the goods are saddened, as it is termed, as a rule, with solutions of salts of iron. These processes, as you will be aware, produce a deep slate colour, inclining to black. After this the goods are taken into the dyehouse, where the processes of dyeing are performed with boiling-hot solutions, in the very large dye vats, which are represented in the drawing before us. These vats are made in two sizes. The smaller one is capable of dyeing 40 pieces, and the larger one 80 pieces at once. The drawings will, I think, at once give you an idea of the working principle of the dyeing machines. These vessels are always worked in pairs. In the first the goods are boiled in a solution of bichromate of potash or soda. This process causes the dye to unite firmly with the cloth, and gives a deeper shade of black. In the second vat the goods are dyed with logwood, and in some cases with the addition of fustic. The dye is fixed boiling hot, after which the goods are washed.

Now it is a fact, that in the case of all cotton goods dyed black—no matter what may be the processes or materials employed—when they leave the

on the face side of the goods, like the sample which I now place before you, showing the results attained by the Yorkshire method of preparing dyeing and finishing black cotton Italians. Now the Lancashire method is to finish generally on calenders; and excellent as is the finish produced in that way, it is distinct in every characteristic from that produced by the Yorkshire mode, whilst goods treated by the Lancashire method, in all the processes feel thinner, handle more papery, and, if anyone spends a short time in cutting them up with shears, more especially in the case of coloured goods, he will find the cut is harsh, and gives the idea of dryness and a grating sensation. On the other hand, the Yorkshire-dyed goods feel more kind and clothly, and cut more freely. I think the description I have given will be fully borne out by a careful examination of the two sets of dyed patterns. One set has been dyed in Lancashire, by what I believe is considered one of the largest and best firms, the other set I know to be Yorkshire dyed; and although it is very probable that the quality of the cloths may not be exactly the same, any other differences that exist are more especially due to the

application of distinct principles in the modes of preparing, dyeing, and finishing the goods, in the manner which I have described.

Before concluding my remarks on the dyeing of black cotton Italians, I may refer to the use of fatty matters and alkalis, probably to our mutual instruction. About two years ago three cases of goods were shipped from Manchester, which had been dyed black by a firm whose dyer had either been negligent or inexperienced in this class of work, or else he had employed inferior materials, for although when the goods were delivered to the merchant and examined they were found to all appearance right, and were therefore made up and packed, hermetically sealed, as usual, in tin cases, yet when they arrived at their destination they were covered with a white efflorescent salt, which appeared to have made its way through the whole piece, joining the folds together so as to make each piece a solid mass. Sample pieces were at once sent to this country, where the opinions expressed were extremely conflicting. On examining a sample piece, I attempted to unfold a portion, and found the operation much like skinning a fish, and the white salt, which had a crystalline appearance, turned out to be a mixture of sulphate of soda and fatty matters, partly saponified. I had therefore no hesitation in saying that the fault lay with the dyer, and in pointing out the cause I stated that the dyer had in the last process probably passed the goods through a bath containing some fatty matter, which had been previously mixed with sulphuric acid, and to which had been afterwards added some carbonate of soda,\* and had not afterwards washed the goods out. Therefore on being dried they were strongly impregnated with those substances. Further, that in order to condition the goods for finishing they had undergone a process to make them damp, and this would probably account for the crystals of sulphate of soda, which seemed to have passed all through the cloth, binding the piece as it were into a solid mass. By treating some sound cloth in the manner just described I had no difficulty in producing and reproducing similar effects at will.

There is another point connected with the dyeing of black cotton Italians which is of the greatest importance both to dyers and merchants. I find from some goods that have come under my notice, samples of which I now produce, that some dyers rely almost exclusively, if not entirely, upon copper salts as their mordants. Now, although goods dyed upon such a mordant can be made to present a very satisfactory appearance for a short time, yet when such goods are shipped, as they have been, to distant Eastern markets, the consequences are most serious, for you are aware that the combination between mordant and dye is a very feeble one in the case of such dyes, and you are also aware that logwood, with which all ordinary blacks are dyed, is not itself a fixed dye. Its permanency depends entirely on the application of proper mordants. Now, when copper mordants are relied upon, and more especially if in the last process the dyer uses alkalis or ammoniacal solutions, the copper salts, or otherwise the oxides of copper, continue to exercise an influence on the logwood and fustic (when present), until the black dye is changed into green-olive, for you know that copper salts, logwood, and fustics in proper proportions will dye green-olive on either wool or cotton. But when the evil results from the employ of these articles are aggravated by the presence of materials predisposing the goods to mildew, the consequences become doubly serious, and I am able to place before you a sample

of the results arising from such want of experience. I am not aware that I am committing any breach of confidence in stating that the sample which I now place before you represents a rather large quantity of goods, which no doubt would appear to be a satisfactory black when shipped, I am not aware how long ago, but you will probably admit that the pattern, which fairly represents a case of goods reshipped from the East to Manchester is now green-olive and very badly mildewed indeed. In that condition the goods have no value whatever, and the question which I very recently had to decide was, could these goods be restored to good condition. I replied in the affirmative. The one case which was returned as sample (every end of which was like the pattern just exhibited) I have refinished perfectly, like this second short length cut from the goods.

We will now leave the dyeing and finishing of black goods, and I shall say very little on the treatment of coloured cottons, as I intend to bring before you dyed samples of mixed goods, not merely for the purpose of showing you that when cotton is mixed with worsted it has to be bleached, mordanted, and dyed after the worsted has been dyed, and that such processes must be performed in such a manner as not to affect the colour which has been imparted to the worsted, whether we are dyeing the cotton warp the same colour as the worsted or quite a different colour, and it often happens that we cannot employ either the same method of bleaching, the same mordants, or even the same dyes which are admirably adapted for dyeing all-cotton goods. Now, in dyeing cotton goods with colours you have free choice in the use of the materials. You have only to consider what mordants or dyes will enable you to produce the required colour, and it often happens that two dyers, who are equally successful as regards the results obtained, will be using different mordants, different processes, and even in some cases different dyes to produce the same colour. Therefore I do not propose to raise any question as to what is the best method or what are the best materials for exactly matching any given colour on cotton goods, but I will explain the reason why mixed goods would be completely spoiled if in the bleaching of such goods the kier-bleaching process were adopted, and as the stannate of soda and muriates of tin are much relied on as mordants for cotton goods, I will show you that at least in some important processes neither of these materials can be used as mordants for mixed goods. I will first explain the objections to kier-bleaching in the case of mixed goods. A long experience has proved that the worsted must be dyed before the cotton is either bleached or dyed; therefore the use of such materials as milk of lime, soda ash or caustic, or resin soap, all of which are employed in kier-bleaching under pressure, is quite inapplicable to the bleaching of mixed goods, as all these materials are very injurious to wool, and would make the goods quite tender—in fact, if they were applied to mixed goods under pressure, not only would the dye which had been fixed on the worsted be destroyed but the goods themselves would be rendered worthless. And for these reasons the bleaching of the cotton warp in mixed goods is very simple. It is effected by simply working the goods in an ordinary bleaching solution, and then souring off in the usual way. By this mode of bleaching the dye fixed upon the worsted is not injuriously affected.

Now, with regard to the use of stannate of soda and muriate of tin as mordants, I will show that the use of each of these articles would be so injurious to the dye of the worsted in mixed goods as to render their employ quite inadmissible. I have in these three bottles solutions of stannate of soda, muriate

\* Some dyers treat gallipoli oil with sulphuric acid, mixing the two well, and putting this mixture into the finishing bath, after which they add excess of carbonate of soda.

of tin, and nitro-muriate of tin respectively. The three dyed patterns in my hand have been dyed, one sky blue, with sulphate of indigo; one green, with the same dye and picro acid; and one with alkaline blue. I will now divide each of these patterns into three equal parts, and put one portion of each colour into each bottle, and in a very short time we shall see that the colour of the slips introduced into the stannate of soda and the muriate of tin has almost disappeared, while the colour upon those introduced into the nitro-muriate of tin solution remains unchanged. You have thus evidence that in the dyeing of "shot" or two-coloured effects we cannot use the stannates of soda or muriates of tin as mordants. Now the reason for the change in the colours dyed with indigo is that in mordanting with muriate of tin, which is a protoxide, the latter has the power of depriving the indigo-blue of its oxygen, thereby reducing it to the state of white indigo, as you have seen. The indigo itself is not destroyed—its colour can be restored by repeated washing in cold and warm water—but an unfavourable condition has been established on the worsted. Thirty years ago, when shot effects were first introduced, these unfavourable results puzzled most of the dyers in Yorkshire. When cotton-warp goods were first introduced they were worsted-dyed only. The cotton warp was left undyed, for the very good reason that the dyer possessed no proper knowledge of cotton dyeing, or of the materials and processes necessary to be employed—in fact, it was a matter of much surprise to him to find that when cotton-warp mixed goods were put into the dye-bath the worsted only united with the dye, while the cotton remained white. A virtue was made of necessity by putting the goods upon the market in that half-dyed state, when a freak of fashion, ever ready to pursue novelty, even though it presents itself in the shape of ugly and unfinished goods, in this case created a great demand for the goods in question, which were then known and are still remembered as "Parisian figures." The dyed range which I now place before you fairly represents the class of goods then in demand, and they will clearly convey to your minds the fact that when goods have to be dyed "shots," i.e., two distinct colours, the worsted is first dyed one of the colours, leaving the cotton warp white, as in these samples of the old "Parisian figures," and the cotton warp has then to be dyed the other colour, different from that of the worsted. It is in the application of the cotton dye under these conditions that the intelligence of the dyer must bring to bear upon his work an experience that will give him such a command over the dyes as to enable him to fix any dye upon the cotton warp without spoiling the colour which has previously been fixed upon the worsted; and in order to show you how completely this command has been obtained, even in the use of all the new dyes, I have dyed specially the large assortment of two-coloured effects which I now place before you. So far as I know, most of these effects are quite new, and there is some indication that "shot" effects will once more come to the front. I invite your special attention to the clearness of the contrasts and the brilliancy of the dyes. For your guidance a ticket is attached to each pattern explaining the dyes employed. You have here the brilliant scarlets, crimsons, and oranges fixed on the cotton warp, whilst the worsted is dyed black, navy blue, green, green-blue, and olive, and browns, green-blues, and violets are mixed with a great variety of other colours, so that in the dyeing of these "shot" effects I have subjected the application of these dyes to the severest test; and it affords me very great pleasure to be able to add that the dyes I have employed in producing these

effects are made in Lancashire, and are as full in colour, as brilliant in tone, and as reasonable in price as any produced by the Continental makers. The scarlet and crimson dyes, when united with either cotton or wool, have all the brilliancy of cochineal dye, and they possess the great advantage of being easily fixed both upon cotton and wool, without the aid of any of the expensive materials which are indispensable to the use of cochineal, such as bitartrate of potash and tin spirit. You are probably aware that tartar is the mordant for cochineal, and together they dye brown, and it is only by the addition of tin spirit that the rich red colour of the cochineal is produced; that the great beauty of this dye, which has been held in so much esteem, is due to the presence of one of the oxides of tin, whilst the oranges, scarlets, and crimsons of the naphthol series are ready made or substantive dyes. The production of all those new naphthol dyes has been a great boon to the practical dyer, inasmuch as their application has been far more simple than that of the old ones, more especially as regards woollen goods, with which they unite without the use of mordants. I believe I am correct in saying that the fixing of some of these dyes, both on all-cotton cloths and on mixed goods, has been in the hands of some dyers a source of great trouble and anxiety; and it is a fact, that to the inexperienced dyer difficulties do sometimes present themselves which perplex the judgment, irritate the temper, and quite unnerve the man. However, experience proves that nothing is impossible to the mind of man, and that with a little knowledge of chemistry these difficulties may be easily overcome. I do not mean to say that before a dyer can be successful in using these colours he must be a thorough chemist, or even that the scientific chemist engaged in the production of dyes must be a thoroughly practical dyer, but just as the scientific man should possess a greater amount of practical knowledge in the special branches to which he is devoted, so it is equally necessary that the practical dyer who intends to succeed should possess a fair acquaintance with that department of scientific knowledge which is especially applied to his trade. As I have already stated, it always has been and still is a puzzle to many dyers to know which mordants are the most suitable for fixing coal-tar colours. This question is of considerable importance, and we will spend a short time in considering it. The coal-tar colours may be divided into two principal groups—namely, (1) colours with basic properties; (2) colours with acid properties. The colours belonging to the second group are frequently derived by combining those of the first group with sulphuric acid. The following are the names of some of the principal coal-tar colours divided into two groups just named—*Basic Colours*: Magenta, saffranin, chrysoidine, Bismarck brown, malachite green, brilliant green, aniline blues soluble in spirit, methyl violets, methylene blue, etc. *Acid Colours*: Eosines and other resorcin colours, roccelin, acid magenta (sulphorosaniline), naphthol scarlets, naphthol oranges, naphthalene yellow, sulphomalachite green, blues soluble in water, etc. Colours which possess basic properties have, as a rule, much greater affinity for cotton than those possessing acid properties. The basic colours will dye cotton either with or without a mordant, but as a rule it is preferable to use mordants for these dyes. On the other hand, colours with acid properties do not unite with and dye firmly cotton goods either with or without a mordant, the combination between the two being so feeble that these dyes may be considered, so far as regards cotton dyeing, simply as impregnation colours. Mordants may thus be entirely dispensed with in using these acid colours,

and I consider the use of mordants with them as being, with perhaps a few exceptions, an absolute waste of time and material, and in many cases injurious to the colours. There is only one rational mode of dyeing, or perhaps we may more appropriately say painting, cotton with these colours, and that is by impregnating the cottons with a strong solution of the dye, and then drying the goods without washing, etc. The effects which I have shown you this evening on shots or single-dyed cottons have in every instance, where colours belonging to the second group have been used, been produced without the assistance of any mordant whatever. I think I have now trespassed sufficiently on your valuable time, and I beg to thank you for the indulgence you have shown me in listening so patiently and attentively to my paper.

#### DISCUSSION ON DR. BOURCART'S AND MR. SHARP'S PAPERS.

The CHAIRMAN: We are much indebted to Dr. Bourcart for the pretty exhibition of prints from Alsace and Switzerland. These prints are specialities, and differ from our average prints in style as well as in execution, but on account of their high price and their special character the demand for them is naturally limited. We also have to thank Dr. Bourcart for bringing before us the dyeing properties of anthragalol. This colouring matter, if yet excluded from competing with alizarin, may at some future day be a valuable addition to our dyewares, and it must certainly be interesting to our members to have their attention called to new products which at some future time may become of practical importance. We have also listened with great attention to Mr. Sharp's valuable paper, to whom great credit is due for kindly coming forward with the object of enlightening our minds on a subject which is shrouded in a good deal of apparent mystery. Such a paper as we have just heard must conduce to the placing of the art of dyeing on a much healthier basis, for after all there do not exist so many real secrets in this art, and Mr. Sharp's attempt to put certain matters connected with it on a more scientific foundation is a most praiseworthy one, and the sooner dyers follow this course the quicker will be their progress. Dyers as a body are very conservative in their trade secrets, but the days of secrecy and mystery are passed, and the success of a dyer depends to-day far more on his personal skill and knowledge than on the secrets or receipts inherited from his father and grandfather. Mr. Sharp rightly points out that successful dyers need not necessarily be great chemists, but they ought at least to understand that part of chemical science which has a direct bearing on their trade. Mr. Sharp has shown us several advantages of the Yorkshire dyers, and the superiority of some of the machinery used in the Yorkshire dye-houses; but considering that the art of cotton dyeing is much older in Lancashire, I may rightly presume that in some specialities our dyers excel, and I hope that before long some Lancashire dyer will set us right on this point by reading a paper on Lancashire dyeing specialities. Considering also the very large number of gentlemen who are present this evening, who are thoroughly acquainted with the subject of the paper, I hope that we may get some information in course of the discussion about the mordants best adapted for coal-tar colours. Many dyers only know sumac and tin (muriate of tin or stannate of soda) as being suitable for the purpose, and whatever colours they have to dye, irrespective of their composition and their special character, sumac and tin, for good and evil, are resorted to. The sizing of cotton warps mentioned by Mr. Sharp may also induce some gentlemen to give us the benefit of their opinion; and surely

this is a subject of which we ought to know more in Lancashire than our friends do in Yorkshire, and it will be very interesting to know to what degree the process of sizing is legitimate, for we all know that it is absolutely necessary for manufacturing purposes to put a certain amount of size on the warps. There are several other points in Mr. Sharp's paper which will suggest themselves to you as practical men, and I have now the pleasure of inviting you to give us your opinions on the subject which Mr. Sharp has so ably treated.

Mr. J. CARTER-BELL: It appears to me, from what we have heard from Mr. Sharp, that the advantages which the Yorkshire dyers possess over the Lancashire dyers in the dyeing and finishing of special cotton goods, such as Italian cloth, etc., principally are due to different machinery, and Mr. Sharp, perhaps, will tell us why the treble crabbing machine has not been generally introduced into Lancashire dye-houses.

Mr. HART: Is it the action of the copper which causes mildew, and does it affect the colour only?

Mr. CUNLIFFE: May I ask by what process you restored the colour and afterwards dyed the goods in the ordinary way?

Mr. SIEBOLD: I should like to know whether the damage to the cloth has been proved to be caused by mildew?

Mr. GEORGE E. DAVIS: I have been much interested in Mr. Sharp's paper, especially that portion relating to sizing and mildew, to the study of which I have devoted considerable time. By the appearance of the damaged goods upon the table I feel much inclined to say that the discolorations do not proceed from mildew but from quite another cause. At one time every obscure stain was ascribed to mildew, and by the uninitiated even yet, but I hope the time will soon be past when this state of things is possible. One point struck me during the reading of the paper, and that was the fact of the adhesion of the various folds of damaged cloth. When we come to consider that there was a large amount of sulphate of soda present, it may readily be seen how this took place. Sulphate of soda crystallises with much water, and the crystals melt at a rather low temperature. Under the excessive heat of the tropics it is possible that the crystals were melted, and afterwards recrystallising bound the whole mass together as one piece. I did not understand from Mr. Sharp's paper whether the mixed goods dyed with aniline products were to be considered as fast dyed goods, so far as the cotton is concerned.

Dr. J. GROSSMANN: I am very glad that Mr. Davis has led the discussion into a different path. The question of mordants is a very important one. As Mr. Sharp has admitted these colours as they are at present, are not fast, and it seems to me that there is no mordant known which will fix them, it is a question which requires to be worked out. There are several experiments which have been introduced and which promise to be of some use, and I am very sorry that Mr. Sharp has not made a few remarks upon the new mordants. There are, for instance, the sulphur mordants for fixing aniline colours, and it would have been very interesting to know what effect they have on aniline colours, and how far they improve the fixing of them. I understood Mr. Sharp to say that to a certain extent bleaching deteriorated the goods, but I think that careful bleaching will not deteriorate them. The new way of bleaching by chlorine, if conducted too quickly, is injurious, but if carried out in a right way it is successful. Of course it is a question of time and money. I have noticed that boiling with chromates in dyeing is another process. There are still a great many mordants used for which there

is no necessity—the chromic acid itself, except when it acts with gelatine and so forth. The chromates are used not in the state of chromic acid but as chromic oxide, therefore why not use these mordants in the form of the preparations to which they have to be brought after all. Why should dyers use bichromates? Why not use chromate salts at once?

Mr. GRIMSHAW: The question of mordants appears to me to be the most important chemical aspect of the subject of dyeing. The object of dyeing, I take it, is to place upon the fibre a colour as brilliant and as satisfactory as possible, at the same time as fast as possible. We are all aware that colours will take more kindly and more firmly to animal fibres such as wool than they do to cotton, and this I think is partly due to the chemical nature of the two fibres. There are two ways of dealing with these fibres, one is to treat them in such a manner that by some means you alter the structure of the fibre, and the other way of mordanting these fibres is to cause the dye in a soluble form to combine with the mordant which has been previously placed upon it, and it seems to me that a mode of fixing them could be arrived at by the processes described by Mr. Sharp. Accepting, then, as a fact that one of the objects is to fix these colours upon fibres, I cannot help myself always regretting that so many of the new dyes that are brought before us are, I may say, in quality the opposite of the age in which we live—that is to say, the advantages are rather fast but the dyes are not fast at all. I think we have to thank the manufacturer of aniline dyes for furnishing us with such excellent and brilliant colours that are less costly, and the supply of which is practically inexhaustible, and I do hope that the chemists and dyers making these colours will see that they stick in the cloth.

Mr. SHARP: In reply to Mr. Carter-Bell, I must confess that it is rather difficult to state the reasons why the Lancashire dyers have not adopted the treble crabbing machine. I suppose the Lancashire dyers and bleachers have a method of treating cotton goods which has met with great success, and by this method they have been able to dispense in the dyeing and finishing of some cotton goods with this machine; but then, in the dyeing and finishing black dyed Italian cloth the treble crabbing machine and the Yorkshire mode of dyeing is in my opinion superior, and therefore that branch of dyeing has come to Yorkshire; and to give you a practical illustration, I may tell you that for years 2d. per yard was paid for dyeing these goods black—to-day considerably less than 1d. per yard is paid, showing that it was not the want of profit which kept the Lancashire dyers from taking this class of work. I do not think for one moment, in reference to Mr. Hart's query, that copper salt produced the mildew. I rather should think the contrary. What I meant to say was that some dyers seem to entirely rely on copper salts as mordants for black, and when the goods are shipped to distant markets the copper salt, or probably the copper oxide, continues its action on the black dye, and ultimately changes it into a green or olive. I do not think that Mr. Cunliffe's question comes within the scope of my paper, and acting on the advice of the chairman I decline to answer the same. Mr. Siebold desires to know if the damage to the cloth shown to you has been proved to be caused by mildew. I must tell him that I have not microscopically examined the cloth, but from its appearance I would judge the red spots to be due to mildew. It is remarkable that those parts of the cloth which were nearest to the boards of the cases were worse spotted than the other parts. The principal question which I had really to decide was if these goods could be restored to their original colour; and as I

have shown to you I succeeded in this, and I have no doubt in my mind that the change of colour from black to olive was caused by the excessive use of copper salt used as a mordant. With regard to the use of bichromates mentioned by Dr. Grossmann, I must say that dyers have to use that which is offered to them by the chemists; and although I am not prepared to deny the probability of the chromates being cheaper, I do believe that at the present exceedingly low prices of bichromates it will be difficult to get anything cheaper. It is quite true that the injury caused to the cotton by bleaching entirely is a question of degree, and the longer you treat the cloth and the stronger the bleach the more injurious is the effect, and *vice versa*.

## Newcastle Section.

The election of officers for next session took place, when the following gentlemen were elected as officers for Session 1881-5:—

Chairman: J. C. Stevenson, M.P.

Vice-Chairman: B. S. Proctor.

Secretary and Treasurer: J. T. Dunn, M.Sc.

Auditor: N. H. Martin.

Committee:

P. P. Bedson, D.Sc.

G. T. France.

C. H. Gimmingham.

John Glover.

A. S. Herschel, M.A.

John Morrison.

John Pattinson.

H. R. Proctor.

W. W. Proctor.

J. P. Stark.

T. W. Stuart.

The discussion on Mr. H. Proctor's paper on "Improvements in the Methods of Estimating Tannins," and on Mr. Gimmingham's paper on "Improvements in Sprengel Air Pumps," was adjourned until the next meeting of the Section.

## Glasgow and West of Scotland Section.

Chairman: Ed. C. C. Stanford.

Vice-chairman: Professor Ferguson.

Committee:

George Beilby.

Professor Crum Brown.

J. Christie.

Dr. John Clark.

Professor Dittmar.

George G. Henderson.

George M'Roberts.

James Mactear.

Professor Mills.

James Napier.

T. L. Patterson, jun.

J. B. Readman.

Dr. Edmund Ronalds.

F. J. Rowan.

R. R. Tatlock.

Dr. William Wallace.

Hon. Treasurer:

J. J. Coleman, 15, West Nile Street, Glasgow.

Hon. Secretary:

Dr. James J. Dobbie, Chemical Laboratory, University of Glasgow.

MEETINGS FOR 1881.

APRIL 8TH.—(1) On Algin. By Mr. Stanford. (2) On some Points in the Technology of Oil of Vitriol. By Mr. Mactear. (3) On Nickel Vessels for Chemical Operations. By Professor Dittmar.

APRIL 29TH. (Special meeting)—Discussion on International Methods of Testing and Sampling. Introduced by Mr. Tatlock.

MAY 13TH.—(1) On Different Methods of Producing Cold Artificially. By Mr. Coleman. (2) On the Composition of Tobacco. By Dr. Clark.

## INAUGURAL ADDRESS BY THE CHAIRMAN,

ED. C. C. STANFORD, ESQ.

WHEN the British Association met at Dublin in 1878, a well-known professor there, who combines the highest scientific attainments with a delightful sense of humour, and who takes a fatherly interest in the local Zoological Society, undertook to introduce the noble animals to the British Association. He afterwards performed the much more difficult task of introducing the British Association to the noble

animals. The result of the latter introduction was highly disappointing—the noble animals were not at all impressed with the dignity of their human types. He has assured us that a vast amount of eloquence was necessary to convince the lions that there was anything remarkable or worthy of imitation about any of the great scientists. One old lion is said to have remarked (of course in his own language) that, in his opinion, they were a very average lot, that their looks were nothing to boast of, and that they talked a vast quantity of twaddle. The appearance of the president did not frighten him, and it is said that he even went so far as to remark that although he were a storehouse of valuable and extensive information, he thought if left alone with him for a little while he could acquire and digest at any rate the substance of it. Now, there is no doubt the lions have some noble qualities in which scientific man is deficient. One of these is the heaven-born gift of silence—they do not talk. My position this evening is somewhat like that of my friend the professor—I have to display the earthly gift of talking; you, on this occasion only, to reflect, the heavenly gift of silence. That, however, is your fault and not mine; and it is some comfort to me to reflect, that however much you may be dissatisfied with the medium of introduction, you are not allowed, again, on this occasion only, to criticise too severely his parts of speech. You have accorded me the happy privilege of presiding over the first session of the first Scotch Section of the Society of Chemical Industry. It is my pleasant duty, therefore, to introduce that Society to you, and my still more pleasant duty to introduce you to that Society. I have this great advantage over my friend the professor, that however much his newly-made acquaintances might mutually benefit each other at a distance, a too intimate mixture would be scarcely desirable. There might be a good deal of decomposition, and a considerable rearrangement of atoms and molecules, perhaps tending to an increase of carnivora at the expense of science. In our case it is different, for I am certain that the more intimate we become with our English friends the more we shall like one another, and that every atom we add here to the chemical industrial molecule will so strengthen it that very considerable outside forces will be unable to decompose or even to discompose it.

The Society of Chemical Industry was only established in June, 1881. It is not yet, therefore, three years of age, but in that short period it has risen to a membership of over 1,500, and it contains among its members chemists and others engaged in every variety of work in any way connected with the science. The Society publishes a most valuable monthly journal, the excellence of which must be admitted by all who peruse it, containing as it does not only the papers read before the Society, or its sections, but also a complete abstract of papers, communications, and patents relating to technical chemistry. The main object of the Society is to bring together, by personal contact where possible, and for interchange of ideas, those connected with any branch of industry requiring chemical knowledge. This, in a broad general sense, makes the Society extremely comprehensive. Scarcely a manufacture exists which does not at some point or other touch the science of chemistry, and every year adds to the number of manufacturers who find it advisable, and indeed necessary, to consult or employ a chemist. Another object of the Society is to promote good fellowship amongst chemists of all denominations; and I claim for it that it has already made wonderful progress in bringing a class of men together who have been hitherto rather inclined to hold aloof from one another. I speak particularly of large chemical manufacturers.

The meetings of this Society have shown that there is very much to be gained and nothing to be lost by the discussion of the faults of old processes and the advantages of new ones. These meetings have already resulted in some unity of action on common grounds, and this tendency is sure to increase. There is also a great advantage to manufacturers to meet professional, analytical, and other chemists engaged in widely different occupations, because those who make one large chemical are very apt to run in a groove, and not think of a manifest improvement which may at once occur to a skilled outsider. We all know how long the railway engineers insisted in running on their unjointed rails before they could be made to believe in the practical application, much less the advantage, of the coachmaker's celebrated fish joint, and which they deem now an absolute necessity. With the object of insuring good discussions on a wide basis, the Society has always welcomed strangers at the meetings, and its members are glad to hear any who can throw a side light upon the subject, knowing as we well do that these side lights are often the best to bring out the shadows. The annual general meetings of the Society, held in London and Manchester, have done much to promote intercourse among chemists, and no doubt the next to be held this year, in Newcastle, will be equally successful. The Society has already sections in London, Liverpool, Manchester, Newcastle, and Birmingham, and we are met together this evening to inaugurate the last, and I hope not to be the least, that for Glasgow and the West of Scotland. The number of members in Scotland are now 158. Of these 109 have joined this Section, and over 50 have been added within the last month through the officers of this Section. A rough analysis of these numbers shows the members to be made up as follows: Professors and demonstrators of chemistry, 15; analytical chemists, 25; manufacturing chemists, 69; chemical engineers, 8; chemical merchants, 8; chemists engaged in dyeing and printing, 10; chemists engaged in iron and steel, 5; chemists engaged in oils and soaps, 9; pharmaceutical chemists, 3; metallurgists, 2; chemical apparatus maker, 1; alkali inspector, 1; doctor of medicine, 1; total, 158. Further analysis of the manufacturing chemists would again divide their manufactures into that of almost every known chemical product from sugar to dynamite. We like to manage our own affairs in Scotland, although, with all our agitation, we have not yet got our Secretary of State. With our Section, however, no agitation is necessary—the General Council in London is anxious to give us perfect liberty, and we have therefore not only a secretary but a committee of our own; and I have no doubt they will be glad to find at head-quarters that we are self-supporting. There is little need to introduce our committee there, for many names in it are known far beyond Scotland; and I think all will admit that they are a thoroughly representative body, and that they give an earnest that we shall do some valuable work. Two of our most distinguished Edinburgh chemists have joined the committee. We have endeavoured to fairly balance professional and practical men, and I may truly say that with us honours are divided. It is only fair, however, to you in this introduction to remark that the Scottish lions, though generally reticent, have always spoken to some purpose on chemical and other scientific subjects.

The Chemical Section of the Philosophical Society of Glasgow has been established over fifteen years, and during that period has enriched the journal of that society with a number of valuable communications, and added many a page to the *Chemical News*. It has been instrumental, also, in preserving the memory of one of our greatest native chemists,

the illustrious Graham, by the establishment of the Graham Fund. This fund is intended to afford a Graham lecture and a Graham medal every three years. The first lecture was given three years ago by Professor Chandler Roberts, Graham's successor at the Royal Mint. The second will be given on the 20th of this month by Dr. R. Angus Smith, whose personal reminiscences of Graham will be very interesting. We are proud to know that the first medal awarded for research in chemical technology, although open to all, was presented to our distinguished colleague, Mr. James Maclear, for his researches in chemical technology. We may also lay claim to a most extensive range of chemical manufactures in our district. I believe almost every manufacture is represented, and some which are unknown elsewhere. I was informed by one who had seen all the great exhibitions of chemicals yet shown throughout the world, that our collection got up when the British Association visited Glasgow, and much of which is still in the Kelvin grove Museum, was the finest ever brought together. I need only point to our programme for the short session we have before us to prove that we have no intention of furnishing blank sheets as our contribution to the journal. On the contrary, we shall have some difficulty in getting through our papers in the time. We have therefore all the elements of success, and if the new Section is not successful we shall have ourselves to blame.

As a prelude to the work of the session, I shall not attempt to pass in review or even to sum up the numerous discoveries which have been recently made in chemical industry; to do so would be to repeat our journal, so well has it kept pace with the times. Probably there is no science which has made such gigantic strides during the last fifty years as that of chemistry. If you take down a good encyclopædia of that date, you will be surprised at the small place allotted to a science the boundaries of which are so extensive now. In the Encyclopædia Britannica of 1830, Brewster's edition, the three alkalis, potash, soda, and ammonia, occupy little more than a page. They are described under the names of the vegetable, the mineral, and the volatile alkali, and it is curious to read, so late as this, of the recent discovery of the metals potassium and sodium by Mr. Davy, and Brewster's remarks thereon. He says: "These results, not yet sufficiently familiarised, and at war with all our late anticipations of the nature and composition of the alkalis, still surprise us." It is curious to read in the same work that soapmakers were then indebted to kelp or barilla for their supply of soda, and of this, kelp only contained 2 to 5 per cent. The importance of analysis is alluded to in the statement that for want of it "some buyers gave £8 per ton for kelp containing 4½ per cent. of soda, and £11 11s. for kelp containing less than 1 per cent. of soda," but the soda must have cost the soapmakers then what would be equal to £80 to £100 per ton for soda ash. A vast change has come over our country since those days. The annual value of the production of these three alkalis is now counted by millions of pounds sterling—the Leblanc, and later the soda ammonia process, for soda; the Stassfurt mines for potash; and the gasworks, and soon, probably, all works burning coal, for ammonia. Anyone who left the earth fifty years ago would now find everything touched by the busy hand of man completely changed. He would have to go into the country and hear the song of the lark, and see the blush of the rose, to find anything familiar to him. Fifteen years, however, before this date, there were chemical works here. The Messrs. Turnbull, of Camlachie, were making wood products. Acetate of lead was then £112 per ton, acetic acid and naphtha 10s. a gallon, charcoal £7 per ton, and Prussian blue 5s.

per pound. They also made bichrome in 1820—it was then sold at 20s. per pound. Some of the fluctuations in prices have been very extraordinary, but in nearly all the tendency has been to largely diminish cost of production and price, and some manufactures have been completely revolutionised by the discovery of new sources of raw material—for instance, the Stassfurt mineral, reducing the price of muriate of potash from £27 per ton to £7 per ton, and bromine from 40s. to 1s. 3d. per pound; the Peruvian caliche, reducing iodine from 40s. to 5s. per pound; and now we read of that wonderful country, California, having mountain ranges of pure alum and pure sulphur. It is rather difficult to compete with such titanic factories. Pleasant, however, as it is to look back and mark the gigantic strides of fifty years, I would rather take courage and look forward; and however much we may congratulate our countrymen for their large share in the great discoveries which mark that advance, it may be more healthful and more politic to see if we are really still ahead in the race. We know that even where as a nation we have been the pioneers we have allowed other nations to outstrip us—for instance, in our boasted postal communication, which in some outlying parts of our island is wretched, and we have not yet the halfpenny letter nor the sixpenny telegram. It is quite the popular fashion now to believe in the power of chemistry to achieve great things—everybody believes in it in a general sort of way. But do we really believe in it? and if so, where is the evidence of our faith? What do we do to extend its boundaries, to increase our knowledge—in short, how do we encourage original research? Does our government believe in it? if so, how much? We all await with impatient interest the report of the Royal Commission on Technical Education, in which our first president, Prof. Roscoe, is so energetically working. Does anyone doubt, however, that the report will be sadly against our negligence in this direction? When we read of a magnificent laboratory for analytical and technical chemistry of great architectural beauty and of splendid internal arrangement, to be erected at a cost of £70,000, we know that it is not for us, it cannot be in this wealthy country—we must go to a much smaller, a much poorer, but a more intelligently governed country for that. I allude to the new laboratory in course of erection at Zurich by the Government of Switzerland.

If you talk to John Bull about the importance of setting chemists to work to verify the atomic weights, you will find an impatient man with his pockets closely buttoned; but if you propose to him a process, however absurd, by which quicksilver can be made into real silver, or by which a gold sovereign can be easily split up into ten silver half crowns, you will secure an open-mouthed listener; indeed, if the process be plausibly described and thoroughly impossible, you may perhaps put your hands in his pockets and turn them inside out—at least it has been done over and over again. We have only just begun as a nation to teach our people to read and write, and it is only quite recently that we have formulated any laws against ignorance. As for anything higher, while other nations have had excellent higher-class and technical schools, we are only beginning to think about these. But we are at last waking up, and no doubt when we do set about it, as usual, we shall not underdo these. Scotland is to be still ahead, for only last week the Peterhead fishermen preferred a request to the Treasury, not for better nets, not for safer harbours, not for finer piers, all of which they want, but for further facilities to aid scientific inquiry into the habits of the herring. I do not know how many thousands of years

this most ancient of industries has been carried on, but it is the occupation on which a large portion of our population live, and it is refreshing and encouraging to find that at last they themselves think it advisable to know something of the habits of the fish they want to catch. Probably, however, the Government will have no funds available for such trifles. The fact is we must have compulsory laws to teach our people. Our Education Act would be little use if it were permissive and confined to those who wanted to learn. According to the *Pall Mall Gazette* France has 30,000 school libraries and 4,000 free public libraries. We have only 96 free public libraries. Even in this city, where private benevolence has done so much in the provision of free public libraries, we cannot get the Act adopted to house the books properly, and probably we never shall as long as it is permissive. Rates for educational purposes are sure to have a marvellous reflex action upon the habits and intelligence of our people, and will pay them a hundred and a thousand fold. Our people have a coarser, rougher way of enjoying themselves. Our annual drink bill amounts to £120,000,000. It is painful to reflect what an amount of rational enjoyment might be got out of even a small proportion of this expenditure, if it went to museums, colleges, libraries, and other public sources of intellectual amusement and instruction; yet most of this sum is absolutely within the power of the people to spend as they like. Every employer of labour in this district knows what the vacant Monday after the pay means to himself and his men, and that higher wages do not always imply greater comfort or enjoyment to the workmen. Do we, as chemical manufacturers, really believe in original research? and if so, how much? Where is the evidence of our faith? What do we do towards verifying the atomic weights on which our products are bought and sold, and on which all our manufactures are based? In one of our leading shipyards there is what is called a scientific department, with Froude's tank erected at great cost, with all necessary apparatus and a scientific staff. It is quite distinct from the general work, and devoted entirely to experiment. If that be advisable and necessary in mechanical work, how much more is it necessary in chemical manufactures? But where is the large chemical works that has such a scientific department? Where shall we find a laboratory which has over its portals without "Original research," and which has for its motto within "Experiment, experiment, experiment"? Where shall we find a laboratory which does for any of the chemical manufactures what the Rothamstead laboratory has done for agriculture? The splendid series of researches which have adorned the proceedings of the Royal Society for so many years, and rendered the names of Lawes and Gilbert famous, prove the value of that laboratory. The honour paid to Sir J. B. Lawes shows that even this country can recognise the value of such work—after it is done; and I am very glad to see that Dr. Gilbert has just been appointed Professor of Rural Economy at the University of Oxford—rural economy being Oxford for agriculture; and it is a Greek culture of rather a novel kind for that great University, and shows an awaking more and more to the claims of science. The idea of a chemist at Woolwich was considered extravagant and unnecessary at one time, but the large scientific establishment now required there shows that in the view of our practical nation it has paid its expenses over and over again. The highly-deserved honour bestowed on its distinguished head, our late President, Sir Frederick Abel, shows again that our nation can appreciate the value of such a great work—again after it is done. We are all wise

after the fact. But are we really convinced that a scientific department is absolutely necessary in manufacturing industry—that is, to us, will it pay? If we profit by past experience, it will certainly form an important feature in the ideal chemical work of the future. Let me illustrate what I mean by a reference to any works, say to gasworks. Of course where other things are equal, the work will pay best where the greatest attention is paid to fulness of output, to economy of labour, of fuel, and of general expenses; but one manager might occupy much time in seeking the cheapest method of getting rid of his waste products. He may have made an excellent contract extending over a term of years for their disposal, only to find out afterwards that he has lost the raw material for a valuable series of new products. I will assume that another gasworks had chemists constantly working on new ground, and that they had discovered the value of the ammonia and the tar which the other was seeking to get rid of as a nuisance. The chemists might or might not have discovered the coal-tar colours, but they would certainly have utilised the ammonia and tar, and it would not have been a subject of discussion now as to whether the lime should be put in the retort instead of the purifier. There can be no doubt as to which of these works would pay best. This is without in the least undervaluing those actual business habits which succeed everywhere in everything. Such instances might be indefinitely multiplied, and the moral is, Don't starve your laboratory; for while you are building a large factory on the usual approved principles for making some marketable product, full of devices for labour and fuel economy, some pale-faced student in a far-off foreign laboratory may be patiently, quietly, but surely undermining the whole fabric.

Now, assuming its value how is this original research to be taught? There is one thing we can never teach, and that is originality. According to Carlyle our population consists of so many millions, "mostly fools." It is bold to differ from such an authority, but this expression has always appeared to me a rather unfair and indirect hit at the fair sex, who form the majority, and the representative of that sex that he knew best was by no means a fool. If, however, the observation ran as so many millions "mostly level," many would endorse it. Nature has always a great tendency to return to a common pattern, and a man whose stature is head and shoulders above his fellows is a marked man all his life; nothing in his surroundings suit him—they all seem to be made for somebody else. So it is with the mind, you cannot crib and confine a great mind, you cannot cram it into the small places of other men any better than you can squeeze a man into a baby chair—its originality overflows and impresses itself on all he says and does. Such men will always be scarce: they mark epochs of thought. Genius may be an infinite capacity for taking pains, and many may attain to it; but a Faraday and a Siemens are men of a generation. No education that we can devise will create such men, and if it is genius in others it is inspiration in them. In fact, it is most probable that our method of education by pass examinations may have a directly opposite tendency. It will certainly level up the majority of the masses, but it may level down the minority who ought to go up higher. Our educational machine, which cuts all its intellectual straws the same length, has an undoubted tendency to lop off the big heads of the long ones. Professional crammers have proved that "an egg shell may be made to look very like an egg." Original research, then, like exploration, is a

very difficult thing to teach. It is easy enough to go along a road that is well lighted, especially if you know the way, but when you come to the end of it, and have to explore a new territory with little light to guide you, then the difficulty commences. The usual experience is, although our chemical schools are rendering it easier, to get young chemists for all ordinary work. Those who have the talent for original investigation are scarce. And who is to teach it? Our professors say they are too much occupied with their present classes; the analytical chemists say they are too much engaged in analytical work, and we the manufacturers in practical applications; but all can assist, and a perfect study of each separate branch is necessary. Original research demands the highest theoretical knowledge of chemistry, the most intimate acquaintance with the best analytical methods, and for use on the large scale the most thorough practical knowledge of the branch known as chemical engineering. The three talents are different, and are not often found to perfection in the same individual. I am doubtful if any technical college could teach this important branch of chemical engineering, and it is here particularly where practice in a chemical works is necessary. In dealing with the wide range of substances, with such various properties, we require a knowledge of strength and properties of materials which is quite special. Platinum, silver, nickel, copper, lead, antimony, zinc, iron, and other metals are all pressed into our service. Vessels of stone, brick, porcelain, lead, and iron of all sorts and shapes are employed. Even our artisans must be the best that can be obtained. The ordinary plumber with his soldering iron is no use to us. It takes a bricklayer with a head on his shoulders to build our intricate furnaces. Even our mason must be able to work the hardest of stone. It is no ordinary kind of engineer that we require when we have to pump such liquids as oil of vitriol, hydrochloric acid, and caustic soda, or exhaust such gases as chlorine, sulphuretted hydrogen, sulphurous and carbonic acids. All this means a pretty wide range of experience, and one impossible to learn theoretically. The advantage of a scientific laboratory in a chemical works is that this knowledge of materials is close at hand, and nowhere else could the great difficulties in the application of new knowledge to new manufactures be so easily worked out. We all know that some reactions which succeed in the laboratory are impossible on the large scale. On the other hand, it does sometimes happen that difficulties in the laboratory disappear in the works. Take, for instance, the ease with which large quantities of chlorine are manipulated without any escape, and the many instances in which the influence of large masses of liquid or solids assist reactions. Great as was our President's discovery of the Weldon process it seems to me the enormous difficulties, patiently overcome in the invention of the necessary apparatus to work it on a large scale, make the discovery far greater. The actual discovery of the Bessemer iron process, which has so revolutionised the iron industry, and which is a strictly chemical process, appears to me to bear only part of the merit due to the wonderful mechanical contrivances invented to work the process on such an enormous scale by that talented inventor.

It appears to me that what our schools have mostly to aim at is the widest possible teaching of chemical and physical science—I mean that the science of chemistry should be taught to all as a portion of primary education; there is no easier means of bringing out the reasoning powers of a boy than by qualitative analysis—and that the highest branches of chemistry and physics should be thoroughly taught to those who intend following any chemical work. We want

young chemists so thoroughly illuminated that they carry a light with them everywhere and into everything, not, if I may use the simile, to "strike only on the box." Our next generation of workmen will, I hope, be an educated race, and we may be able to get foremen who are well up in chemistry. I am not at all afraid that the majority will ever be over-educated, and as for overwork, I fear that for the teachers much more than for the scholars. At present there are many branches of manufacturing chemistry almost entirely in the hands of the Germans and French, especially those where a thorough knowledge of organic chemistry is required. We have not the workmen and we have not the foremen in this country at present, neither the army nor the non-commissioned officers that can undertake such work. In an excellent paper read by our secretary, Dr. Dobbie, to the Glasgow Philosophical Society last week, he has collected statistics of the sources of the papers abstracted for the *Journal of the Chemical Society*. I would refer all interested in this subject to the paper itself, which, when published, will be widely read. He has allowed me to quote, however, one of the results. Here counts the total number of papers published in 1882 at 3,000. He compares the years 1872 and 1882, and shows that in the former year the abstracts of papers were of English 151, of German 809, which in the latter year increased to 232 of English and 1,442 of German. But of these the organic researches were in 1872, 31 of English, 67 of French, and 296 of German; in 1882 they were increased to 59 of English, 96 of French, and 574 of German. So that in this, the most difficult department of chemical knowledge, the Germans retain their power of creating ten times the number of papers that we do, and the French are also ahead of us; and these do not represent the actual total number of papers published abroad, but only those considered to be worth abstraction by English chemists connected with our Chemical Society. Dr. Dobbie points out that the papers show that we are specially behind in physiological and agricultural chemistry. This must be patent to all chemists. Researches in animal and vegetable chemistry are peculiarly difficult, and amidst all our voluminous manuals on theoretical and analytical chemistry we have scarcely a single book by any English author, except translations, on proximate organic analysis. There is a considerable amount of chemical work which is much required, and which, although it may be called research, is not original research, but is equally important, and this valuable work is especially that which, on account of its want of novelty, is not particularly attractive. I allude to the verification of methods, to exhaustive studies of combining equivalents, boiling points, vapour densities, etc. Although not the actual explorers in the dark mine of science, these workers prepare the tools, level the ways, and provide the lights—their work is absolutely necessary, and they should share the spoil of the victors. It is good work for the higher-class chemical students in the training colleges or universities of the future; and here I would mention that the delicate manipulations of quantitative analysis appear to me to add another to those numerous opportunities now being discovered for the application of the higher education of women.

One of the important subjects which will be brought before you this session is the question of commercial analysis. It is one which presents many difficulties. You are aware that Prof. Lunge, of Zurich, has addressed a letter to most of the European chemical societies with the view of securing an international agreement in analytical methods, in the statement of results, and in sampling. The subject is not at all new to us here. In 1874 we discussed it at the Chemical Section, and a resolution was then placed in my

hands asking the British Association to appoint a committee to inquire into the question. The Newcastle Chemical Society, now a section of the Society of Chemical Industry, held a meeting at Newcastle, at which Dr. Lunge was present, and adopted, on our request, a similar motion. The committee was appointed, in 1874, by the British Association, at Belfast, and consisted of Professor Dewar, Mr. Fletcher, with Mr. Allen as secretary, and myself as chairman. The two substances named in the report were potash salts and phosphoric acid. We addressed letters to all the best known analysts at home and abroad. The answers to some of these form amusing reading even now; but a good deal of valuable information was elicited, and all showed the great want of uniformity which prevailed, especially in phosphates. A few analysts refused to reveal their methods; one, at least, would not, as he said, "pour la gloire" alone. The researches on the phosphates were not fully completed—we found the field too extensive; but the report on potash was finished, and we fully proved that the methods of some of the German chemists must be 1 to 2 per cent. higher in the estimation of potash salts than they ought to be, especially where much soda salt was present. The analyses are fully detailed in our report. But what is the result? It was stated at the meeting of the London Section the other day, when this question was discussed, that the Stassfurt manufacturers have formed a syndicate, and determined to sell their potash salts only by an analytical method which we consider too high; and as our consumers here are equally determined not to buy by that analysis, they will allow for the difference in the price, or a broker will act as the medium between them, and buy by one and sell by the other analysis. The great question is whether the makers will follow the new analysis when the old one has been found to be wrong, if, as in the case of soda, for instance, it has been long the custom, or it pays better, to sell on a wrong method or a wrong atonic weight. If we cannot agree in this country on so simple a matter as the actual amount of soda in soda ash, which differs in different parts of the kingdom, what are we to do with the phosphates, for instance, whose names are legion, and what with the international weights and measures? Then, again, would it not be better to base the prices of all articles on 100 per cent. or purity? In many instances the price would then be an easy measure of the quality. The subject presents many lines of inquiry and discussion, and I do not wish to anticipate our special meeting called to consider it, particularly as it will be introduced by Mr. Tatlock, who was associated with it in the British Association Committee. But I would just point out that this is one of those questions in which, in this country at least, the Society of Chemical Industry, drawing its members from all classes of chemists, alone has any chance of doing any good. It is a very proper subject for our discussion, and I have no doubt that at any rate some improvement and advantage will result. To have chemists stigmatised as high and low, so that brokers prefer to sell by one and buy by the other, is a scandal to our exact science that we cannot too deeply deplore.

One general subject I would briefly refer to, although it affects other British manufactures as well as our own—that is, the heavy uneven charges and monstrous mismanagement of our railways. I refer to it here because the subject has been brought prominently forward by a once well-known member of this Society, Mr. Peter Spence, of Manchester, now gone to his rest. A pamphlet has been published containing his evidence given before the House of Commons Committee on Railway Rates. It is entitled "How

the Railway Companies are Crippling British Industry and Destroying the Canals." I would advise all to read it. The details given there of the unequal rates charged in different parts of the country, and the excessive nature of them all, are fully exposed. It is remarkable that it should be so much cheaper for us to send goods to India or America than to London, and that goods should be cheaper in one direction than in another. The American railways are made to open up the country for carrying goods to the ports; ours appear to have been made to throttle our inland commerce. Anything is possible on a railway, as in the case of the railway company that charged so much more carriage for the secondary battery after it had been charged with electricity to make up for the additional weight. The late Mr. Spence strongly protested against the railway companies increasing their monopoly by buying up canals, as some have done in our district, urging that it would be far better to enlarge and extend the canals through the country, a large steam lighter on a large canal being the cheapest known mode of conveyance. The "cold without" of the canal boat is cheaper to keep up than the "hot within" of the locomotive. I remember much interest being excited by an experiment shown by Mr. Spence, before the chemical section of the British Association, at Exeter, in 1869, in which he raised the temperature of caustic soda to 250° Fahr., by passing into it steam at 212° Fahr. Practical application has recently been given to this discovery in Honigsmann's fireless caustic-soda boiler and engine.

The alizarine industry, one of the last triumphs of organic chemistry, is particularly interesting to this district, where we have so many Turkey-red dyes. The manufacture has been almost exclusively in the hands of German makers. A published statement of one of the works gives the net profits of 1882 at £360,700, after writing off to a sinking fund during three years the sum of £250,000. I may add that this work is remarkable for its very large and expensive scientific department, and the profits give us an idea how much we have been compelled to contribute to the support of that establishment. This manufacture has always been particularly urged against our home chemists, because most of the anthracene is exported from this country and then reimported as alizarine—that is to say, that in addition to the discovery the German chemists have manufactured the new product, and have shown us how to utilise one of our raw materials, and charged us pretty heavily for our want of chemical knowledge. It should not be forgotten that neither alizarine nor indigo was discovered by accident, but by patient investigation on well-known lines, and both result from a long series of separate discoveries by different experimenters. The amount made is now about 1,300 tons a month of 10 per cent. alizarine, of which 600 to 700 tons are consumed in the United Kingdom. It is some consolation to know that two firms in this country, Messrs. Hardman and Company, Manchester, and the British Alizarine Company, London, are now making a considerable portion of this home consumption, the latter now increasing from 200 to 300 tons per month. The total make is worth about £1,560,000, but this would require about four times that value of madder, which could not be produced. Artificial indigo is now also made in Germany, but here the yield of the plant is much larger than that of alizarine from madder, and the artificial product has more difficulties to contend with, but it is imported and used. Its introduction is only a question of time, and it may lead to further discoveries and better shades of colour. In 1883 the value of our imports of indigo, however, amounted to 100,713 cwt., valued at £2,467,083. We also imported of cinchona bark 117,325 cwt., valued at

£1,429,261, and of opium to the approximate value of £500,000. The value of these three imports amounts to £4,396,344. The total export of alkali amounted during the same time to 6,946,615 cwt., valued at £2,124,834. Thus the value of the imports of these three drugs amounts to more than double the value of the export of our largest chemical product, and the cinchona bark import for the year is £400,000 less than usual. This shows the great importance of these products, and yet it requires no prophetic gift to predict that all will be ultimately superseded. Indigo is already produced in the laboratory. Quinine and morphia are both gradually nearing measurable distance. Are these victories to be scored to us, or must we stand by and let the foreign students of organic chemistry snatch them from us? The replacement of these natural products, madder, indigo, cinchona bark, and opium, by artificial alkaloids produced in the laboratory, means the restoration of enormous tracts of land in different parts of the world devoted to the growth of these products, and in many instances freeing them for the cultivation of cereals and other foods. These are only two of the many prizes yet to be won. We also imported last year chemical manufactured products to the extent of £1,544,694. I have not the details of these at hand, but they represent a large number of finer chemicals that ought to be made at home. In therapeutics there is a very large field for the new organic products of the laboratory. Every day adds to the physician's armoury some new sharp weapon. Kairine or oxychinoline-methyl-hydride has been found an efficient substitute for quinine. Iodoform is now largely used as an antiseptic. Even the commoner metals are not yet worked out for medicines, for nickel in the form of bromide has just been introduced for the treatment of nervous diseases.

In quinine and morphia and chloroform some of our well-known manufacturers in London and Edinburgh hold their own against great odds. Some concession might be made to the manufacturers of these finer chemicals, especially chloroform and the alkaloids, by allowing the use of duty-free spirit, in which the German chemists have a great advantage. I cannot see any real objection to this, as the excise officer would have the entrée to the works. Methylated spirit is no use for some of these manufactures, and when men want to drink, it goes down the arid throat as easily and quickly as any other. Indeed, according to Dr. Richardson, methylic alcohol from its lower boiling point is more wholesome than ethylic; and "potable wood naphtha" was one of the chemical features of the London Exhibition of 1862, so that it is easily purified. An agitation is now going on in America for duty-free spirit for manufacturing purposes. The formation of worts for distilling and for brewing is becoming an important branch of applied chemistry, and there is none requiring more organic research. Cheaper starches, gums, and sugars will be sought to supply the alcohol, and we shall not always sacrifice so much valuable land in cultivating barley to make so little out of it. In 1882 there were 2,662,927 acres of barley under cultivation in the United Kingdom, besides an import valued at £5,541,498. Perhaps even some day we may have dry British wines with the pure delicate flavour of our home fruits, when some chemist has discovered a means of completely precipitating the acids which distinguish these fruits from the grape. So much has been recently added to our knowledge of fermentations, and the great economic and social importance of ferments, that it is impossible to predict the extent of the future boundaries of fermentation. Is it impossible to produce gutta serena and india rubber, of which natural products over £2,000,000 worth are annually

imported into Liverpool? I do not mean imitations, but condensed, partly-oxidised, hydrocarbons, as these bodies seem to be. How much longer are we to stick to the old-fashioned method of making cyanide? and when are we to obtain ammonia from the air, if indeed the ironmasters do not make it a drug in the market? Where is our cheap aluminium? We are constantly promised this valuable metal at the price of copper or less, but when are we to get it? The manufacture is now almost confined to one work in France. If it is the case that we are to have two separate pipes for gas, one for heating and one for lighting, we may see a vast impetus given to the use of what is likely to be the domestic fuel of the future, and we may also see the illuminating power so increased that it may light our rooms without so offensively heating them. The deposition of salts by refrigeration, in contradistinction to evaporation, has been very little studied in this country. The subject of refrigeration will be brought before you by our treasurer, Mr. Coleman, whose name is so identified with it. The use of dialysis also is little known here, although a good deal used in the sugar works of France. The vacuum pan, now of very general application, is another appliance little resorted to here in other than sugar works. Electricity also will come to our aid; its use in the precipitation of the more valuable metals seems to be foreshadowed. This may cause more attention to be paid to the solution of weak ores in acids, and their extraction in the wet way. In electric lighting the manufacture of carbons is becoming an important chemical industry, though not as yet to a large extent in this country. In our large alkali works we may look for considerable additions to our mechanical appliances. The revolving saltcake, carbonating, and black-ash furnaces, the filter press, and the hydro-extractor have already done much for us; but we are only on the threshold of the proper use of fuel, and we may ere long be using gas not only for fuel but for driving our engines instead of steam. That ammonia will be largely recovered is now certain, and perhaps it may become a low-priced product; and I would remark here that the ironworks are teaching our chemists to look after their chimney gases. No less than 50 European patents were taken out last year having ammonia for the subject. If cheap there will be many uses for the volatile alkali, independent of those for agriculture and the soda ammonia process, each large outlets. Our President has cleverly summed up the present position of the chlorine industry, and the prospects of competition between the old Leblanc process and its new, or rather its newly-revived, competitor, the soda ammonia process, which has now taken such firm root in this country. His prediction that bleach ought to be £10 per ton has been realised, and much more rapidly than he could have expected; and although other chlorine products have not yet risen in proportion, these are bound to follow. There is no doubt that hydrochloric acid must rise in value, from its increased cost of production, and as new applications are found for it. We must not, however, forget that 70 per cent. of all we make is run into the sewers, and lost as chloride of calcium; and in a similar waste the soda ammonia process is equally faulty. Whether or not chlorine will be produced from chloride of calcium remains to be seen, but if it be the advantage will still remain with the old process. We cannot as chemists, however, look with any complacency on a process as perfect which gives up less than a third of the chlorine available for use. Of course, it is always possible that another bleaching agent may be discovered which may replace chlorine. Peroxide of hydrogen is that which, of all others, is the least objectionable if it could be produced at a low price. Its cost at present,

however, renders it out of the question. The method proposed by Dr. Dobbie and Mr. Hutcheson of separating the chlorine on the cloth itself by electrolysis is a further step in the right direction if it can, as I hope it will, be practically introduced. Again, in the Leblanc process we throw away all the sulphur in the most offensive way. It is a very imperfect process which obliges us to cast away a waste product amounting to as much as the saltcake we use. That this has been done so many years is, to my mind, a proof that we have not scientifically worked out our methods. Schaffner's process, a foreign one, for recovering the sulphur and utilising the whole material, has been worked out and ably advocated by Mr. Chance, of Birmingham, and most of us are familiar with its details. The actual recovery of the sulphur in a saleable form does not appear to have been thoroughly perfected; but the process elicited general approval from a large meeting of alkali makers and technical chemists at Liverpool last year. Many things have happened since they and the pyrites companies have wisely reduced the price of sulphur. This concession may postpone for a time the erection of Schaffner or other plant for the recovery of sulphur. But do not let us suppose that the question is shelved. It seems to me that if the Leblanc process is to hold its own, this important question must be solved, and this waste nuisance done away with. Nothing should be more encouraged than the utilisation of waste. If the man is to be honoured who makes two blades of grass grow where one grew before, should we not give a double measure to him who grows grass where nothing grew before, and even greater honour to him who creates something valuable out of less than nothing, in fact out of a costly nuisance.

One of the desiderata of the day is the extraction of glycerine from the waste leys of the soapworks, and a good many patents have been lately taken out for this purpose. Glycerine has become a substance of great commercial importance, and it has become dear on account of the diminution in the composite candle industry. This is another instance of a valuable product which has always been thrown away in the soap leys to add to the varied contents of the sewers. This reminds me that if any chemist is very hard up for a subject, these sewers, with their chaotic contents, will give him ample opportunity for fine analytical skill, if he essays to pick out from the very cheap mixture a few of its valuable ingredients. A thoroughly scientific pick is required, and one has not yet been forged which will enable him to pick out any pay except "through the nose." If, however, a separate system of small water-tight and air-tight sewers be ever adopted, which will deal only with the domestic water supply and not with the rainfall, even sewage may be worth his attention. Here we have made some progress, this being the only British city, as far as I know, in which the public urinals are utilised for the production of ammonia. The chemists are somewhat in the position of the Yankee storyteller, who says, "If we don't know any facts we kin' make them." Our science has been making facts for the last 50 years, and who shall say where the next 50 years may land us? We must, however, welcome and make the most of every new addition to our knowledge, however apparently trivial. The philosopher has been described as the observer of minute differences. That awful sneer, "*Cui bono?*" which has deterred many a young discoverer, must be thrown away on us. "What is the use of it?" is the first question of ignorance. Our experience of the greatness of little things should teach us rather to ask "What may not be the use of a new fact, however trivial?" If Madame Galvani had not caught a cold,

and the doctor had not ordered her a bowl of frog soup, and if her husband had not hung the frog's legs on a copper hook to an iron rail, we might not have had the electric telegraph. A *cui bono* little thing may some day mean the greatest good to the largest number. The marvellous power of little things is well illustrated in those remarkable microcosms which appear to be the cause of so much human suffering, or perhaps as human lives are not always considered so important as animals or crops, I should refer to the bacteria of splenic fever, or to the tiny fungus of the potato disease, at whose mercy there lies a crop worth generally in this country about £20,000,000. These studies are only in their infancy, and we shall be largely called on to assist in fighting these small plagues. New remedies and new disinfectants will be required at our hands in the sweet by-and-by, when we are to enjoy immunity from all diseases. There is, however, no doubt a reward for all labour, however apparently unremunerative, and at any rate it is a good thing to have something to tussle with. We inherit an amount of chemical knowledge which necessarily divides us into many different departments. The tract bequeathed to us is so large that each has enough to do to look after the cultivation of his own particular field; but it is none the less advantageous that we should all meet together to discuss our various difficulties, and reveal our new discoveries. I augur for the Society of Chemical Industry that its meetings will so bring us together for mutual advice and mutual assistance, and if we do not always succeed in borrowing new tools or obtaining new lights from each other, to help us to lay the difficulties and dig up the underlying treasures, we shall at any rate return to our several fields of labour assisted and encouraged.

And now, in concluding this discursive talk, I would bid hearty welcome to members and strangers who have favoured us with their presence to-night. It is said, "You should never prophesy unless you know," but I do know my colleagues on the committee of this Section, and I can confidently predict that, whatever may be my own failings, they will make this Section a perfect success; and as the health and prosperity of the Section will depend much on the quality and variety of the food produced, I will only preface the intellectual feast which will be laid before you by the appropriate grace—may

"good digestion wait on appetite,  
And health on both."

A cordial vote of thanks to Mr. Stanford for his address was moved by Prof. DITTMAR, seconded by Mr. J. J. COLEMAN, supported by Prof. FERGUSON, and carried by acclamation.

## Journal and Patent Literature.

### I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

*An Improved Boiler or Digester for Effecting Chemical or other Operations.* G. Knowles, London. Eng. Pat 3287, July 3, 1883.

THE boiler or digester which constitutes the present invention is designed for use in such operations as that of digesting raw fibrous materials for paper-making with a solution of sulphurous acid, or of a bisulphite, or with other solutions which attack iron. It is composed of a closed steam-tight vessel, containing another vessel of somewhat smaller diameter, the space between the two vessels being filled or nearly so with water or other liquid. If the inner vessel be filled to the same level as the outer vessel with a liquid or solution of the same

density, the hydrostatic pressure on the inside and outside of the inner vessel will naturally be equal. The upper part of the outer vessel forms a steam chest or dome, and the inner vessel is in free communication therewith, the edge of this vessel projecting upwards, above the surrounding liquid. The inner vessel is provided with one or more pipes or coils, by means of which its contents can be heated by steam or hot water."

*Improvements in Apparatus for the Collection and Condensation of Vapours Evolved in the Manufacture of Indiarubber Goods partly Applicable for Use in the Condensation of other Vapours.* C. A. Burghardt, Manchester. Eng. Pat. 3335, July 5, 1883.

THIS invention relates to apparatus for the condensation of the "naphtha, benzol, or other volatile solvent which is evolved in the form of vapour during the manufacture of Indiarubber goods." The apparatus "consists of a chamber which is divided into a number of compartments by means of partitions, each consisting of a number of sheets of wire gauze, or of thin finely-perforated plates. The said shell is made in sections, and the sheets of gauze are larger than the area of each section, so that the edges of the said sheets project all round or on all sides into the water or cooling fluid with which the condenser is surrounded."

## II.—FUEL, GAS, AND LIGHT.

*The Decomposition of Ammonia by Heat.* William Ramsay, Ph.D., and Sydney Young, D.Sc.

It is well known that when ammonia gas is passed through a red-hot porcelain tube, or when it is exposed to the electric spark for some time, decomposition into nitrogen and hydrogen ensues. Numerous attempts have also been made to bring about the combination of free hydrogen and nitrogen, but the results have not been very satisfactory. The subject has been studied especially by Deville (*Annalen*, 135, 104; 127, 281; 135, 104); and more recently by Donkin (*Proc. Roy. Soc.* 21, 281), and E. Johnstone (*Chem. News*, Dec., 1883). It is also stated in Watt's Dictionary, vol. i., page 183, that ammonia is decomposed by passage through a red-hot porcelain tube containing copper or iron wire, and to a less extent when gold, silver, or platinum wire is employed. The object of the authors was to ascertain the temperature at which the decomposition of ammonia takes place, and to study more carefully than has yet been done the influence of the material of the vessel or tube containing the gas. The ammonia gas was generated by gently warming a concentrated aqueous solution of ammonia, and was dried by passing it through three bottles containing quicklime, and then led through a tube heated by a Fletcher's furnace. The undecomposed ammonia was estimated by absorption in a known quantity of standard sulphuric acid and subsequent titration of the unsaturated acid, while the mixed nitrogen and hydrogen were collected in a suitable vessel and their volume measured. The temperature of the furnace was ascertained approximately by the fusion of salts placed on small pieces of platinum foil lying on the surface of the tube. The results obtained were as follow: (1) With a porcelain tube filled with broken pieces of porcelain—

Temperature. Deg. C.	Mean Percentage of Ammonia decomposed.
500 .....	1.57
520 .....	2.33
600 .....	18.28
620 .....	25.58
680 .....	35.01
690 .....	47.71
810—830 .....	69.5

There was a considerable want of uniformity at the higher temperatures, owing, first, to the difficulty in keeping the temperature of the tube constant, and, secondly, to the variable rapidity of the current, the influence of which was very great, as might be expected, since there is

practically no recombination of the nitrogen and hydrogen to form ammonia. (2) With an iron tube filled with broken pieces of porcelain—

507—527 .....	1.15
600 (current very fast) .....	21.36
600 (current much slower) .....	31.14
628 .....	65.43
676—695 .....	66.37
730 .....	93.38
780 .....	100

(3) With a plain glass combustion tube, lying in the iron tube—

780 .....	0.21
-----------	------

(4) With a glass combustion tube, filled with fragments of broken glass tubing—

780 .....	1.72
-----------	------

(5) With a glass tube filled with strips of ignited asbestos cardboard—

520 .....	2.90
780 .....	100

(6) With a plain iron tube; (a) no oxide of iron present—

780 .....	100
-----------	-----

(b) Tube partially oxidised, and therefore water formed—

780 .....	95
-----------	----

(7) With a glass tube containing several lengths of iron wire—

760 .....	75
-----------	----

(8) With a glass tube containing several lengths of copper wire—

760 .....	2.0
-----------	-----

(9) With a glass tube filled with copper reduced from the oxide, to give a large surface—

780 .....	50.2
-----------	------

The results may be summed up as follow: (1) Under the most favourable circumstances—with an iron or porcelain tube, or a glass tube containing asbestos—the temperature at which ammonia gas begins to decompose lies a little below 500°. (2) In contact with a glass surface, the temperature at which decomposition begins is much higher. (3) The influence of the rate of passage of the gas, or, in other words, of the time of exposure is very great. (4) The nature of the surface of the containing vessel exerts an enormous influence on the amount of decomposition. (5) As might be expected, the amount of decomposition is greater when the surface is increased. Attempts were made to study the influence of time and of pressure on the decomposition of the gas by heating it in closed glass tubes protected by copper wire, copper electrolytically deposited, and sheet copper, but the tubes almost invariably burst. One tube, however, was heated to 780° for six hours without any appreciable decomposition of the gas. It is to be observed that the decomposition of the ammonia was never absolutely complete, for the issuing gas had always a faint ammoniacal smell and an alkaline reaction sufficiently powerful to turn a piece of red litmus paper blue, and this was the case even when the ammonia was passed through an iron tube heated to very bright redness with the blast. This fact agrees with that observed by Deville that the decomposition of ammonia gas by means of the electric spark is never quite complete, the most probable explanation being that recombination of the nitrogen and hydrogen takes place to a very slight extent. When, however, a mixture of dry nitrogen and hydrogen was passed through a red-hot glass tube containing iron filings, or through an iron tube, the presence of ammonia could not be recognised. When the mixed gases were moist, a trace of ammonia was formed, but in this case nascent hydrogen may have been produced by the decomposition of the water by the iron. The authors hope to have an opportunity before long of studying the influence of gas carbon on the decomposition of ammonia, this substance being always present in gas retorts, and practically forming the walls of the retorts.—S. Y.

*Notes on Ammoniacal Liquor.* A Paper read before the North of England Gas Managers' Association, by J. H. Cox, jun.

AMMONIACAL liquor, or "gas liquor," is the watery solution of ammonium salts which results from the distillation of coal, and condenses in the hydraulic main and scrubbing and condensing plant. The ammonia is combined with the different acids, also formed during the process, to produce salts which may be classified as volatile and fixed. These are principally

#### VOLATILE SALTS.

Ammonium sulphide  $(\text{NH}_4)_2\text{S}$   
 Ammonium hydrosulphide  $(\text{NH}_4)\text{HS}$   
 Ammonium carbonate  $(\text{NH}_4)_2\text{CO}_3$   
 Ammonium bicarbonate  $(\text{NH}_4)\text{HCO}_3$   
 Ammonium thiosulphate  $(\text{NH}_4)_2\text{S}_2\text{O}_3$   
 Ammonium sulphite  $(\text{NH}_4)_2\text{SO}_3$

#### FIXED SALTS.

Ammonium sulphate  $(\text{NH}_4)_2\text{SO}_4$   
 Ammonium sulphocyanate  $\text{NH}_4\text{CNS}$   
 Ammonium cyanide  $\text{NH}_4\text{CN}$   
 Ammonium ferrocyanide  $(\text{NH}_4)_4\text{FeC}_6\text{N}_6$   
 Ammonium chloride  $\text{NH}_4\text{Cl}$

of which the sulphide, carbonate, chloride, and sulphocyanate are the most common. The first class of salts yield up their ammonia on simple boiling; the latter require the presence of lime to combine with the acid and set free the base. The proportion of fixed to volatile ammonia varies greatly (see Table I.) in different parts of the plant, the former being found chiefly in the hydraulic main, and the latter in the condensers. The quantity and kind of the ammonium salts depend on the kind of coal distilled, the temperature to which the liquor has been subjected, its exposure or non-exposure to the air, and the manner in which the washing and scrubbing are done. The greater the heat in the retorts the more cyanide and sulphocyanate are, as a rule, present in the liquor. Exposure of the liquor to the air occasions loss of ammonia from conversion of the sulphide and carbonate into hydrosulphide and bicarbonate respectively. Table I. shows how varied is the percentage of ammonia combined with each acid in different parts of the condensing plant. Gas liquor varies in appearance from bright yellow (due to the presence of poly-sulphides of ammonium) through all the shades of yellow to a colourless liquid. The oxidation of ammonium hydrosulphide often occasions a cloudiness from deposition of sulphur. The amount of ammonia present in the liquor is expressed by indicating the number of ounces of concentrated  $\text{H}_2\text{SO}_4$  required to neutralise the ammonia present per gallon. The strength of the liquor by Twaddell's hydrometer is often taken as the test, the number of degrees indicated being supposed to give, when doubled, the ounce strength of the liquor. The fallacy of this test is apparent when we consider that the more free ammonia is present the lower is the specific gravity of the liquor. The saturation test, or simple neutralisation of the liquor with sulphuric acid, is misleading, as it takes no account of the fixed ammonia. The only true valuation is that in which the ammonia is distilled with addition of lime and subsequently estimated. An important work done by the gas liquor is the partial purification of the gas from sulphuretted hydrogen and carbonic acid. On an average one ton of Newcastle coal yields 6½ lb. of ammonia, 15 lb. of sulphuretted hydrogen and 30 lb. of carbonic acid. These two last would require 38 lb. of ammonia to combine with, and as only about 5½ of the total 6½ lb. are available for this, it would appear that about sixth-sevenths of the impure gases are not eliminated. But by repeatedly bringing the liquor into contact with the gas the purification is carried further. Sulphuretted hydrogen is displaced by carbonic acid and remains in solution, while the gradual conversion of the sulphide and carbonate into hydrosulphide and bicarbonate allows the ammonia to remove a double portion of impurity. Table I. gives examples of the purifying work done by liquor. The removal of carbon disulphide from the gas, now for the most part

effected by the sulphide of lime in the purifiers, would probably be accomplished equally well by ammonium sulphide, but the use of the latter would be more expensive, as a certain amount of ammonia would be converted into the form of sulphocyanate, and this is practically useless in the sulphate house. Thus to remove 3,000 grains of sulphur per ton (=30 grs. per 100 cubic feet of gas) about 1,600 grains of ammonia would be used at a cost of somewhat over a penny. This penny would have to be added to the purifying account. The ammonia of gas liquor is generally converted into the more convenient form of sulphate, and here a considerable loss generally occurs. When a large percentage of the ammonia is "fixed" a great deal of it generally goes away in the waste liquor. Table II. (No. 11) gives the analysis of a sample of liquor of which 30 per cent. of the total ammonia was thus lost. No. 14, on the other hand, was particularly good for working, and the loss was only 0.8 per cent. Most samples of liquor lie between these two extremes. In practice it seems impossible, even by the use of a large excess of lime, to drive off all the fixed ammonia, but, nevertheless, there is no ground for the assertion of some that it does not pay to use lime at all. It is a good rule to add 5 lb. of lime per 10,000 grains of fixed ammonia. All this points to the necessity of rigidly analysing the liquor before and after it has been in the still, so as to regulate the supply of lime and the length of boiling. In the course of the discussion which followed the reading of the paper, Mr. Ridley, of Newcastle, gave it as his opinion that it did not pay to attempt to get the fixed ammonia from gas liquor, and Mr. Cox mentioned, further, that at Hendon purifying cost 3.9d. per ton of coal, viz., 2.5d. in lime and 1.4d. in labour, while sulphate cost £5 per ton to manufacture, and they make 20 lb. of sulphate per ton of coal.—A. R. D.

AN American correspondent of the *Journal of Gas-Lighting* sends an interesting communication on the subject of the appearance of naphthalene in a New Jersey gasworks. The appliances stand in the following order from the hydraulic main, condensers, washer, exhauster, purifier, station meter, and are all very large for the quantity of gas made, the connecting pipes being sufficient for five times the quantity. The gas enters the holders at a temperature of about 21° C. Two or three times in the course of the 10 years that the works have been in operation, the inlet of the gasholder has, in warm weather, been choked with a deposit of naphthalene. It was steamed out at first, but last summer appeared again and again. This was while carbonising coal alone, and no canal was used, but as soon as from 3 to 10 per cent. of this latter was added, the inconvenience entirely ceased. It was thus proved then that the addition of canal tends to prevent the formation of naphthalene.—A. R. D.

*Results obtained in the Manufacture of Sulphate of Ammonia and Sulphuric Acid.* A Paper read by Mr. J. Hepworth before the North of England Gas Managers' Association.

THE author, referring to the chances of gas as the light of the future, dwells upon the necessity of cheapening its production by an economical utilisation of the by-products. The following results are from his own experience. Having to deal with 1,750 tons of liquor of 5° Tw., for which he could not obtain more than 10s. per ton, he put up sulphate plant at a cost of £1,300, exclusive of buildings. He thinks, however, that a plant of equal efficiency could now be erected for £750. Last year's work shows the following particulars: Liquor per ton of coal=28.36 gallons of 5° Tw. Sulphate of ammonia produced per 100 tons of coal=1 ton 1 cwt. 0 gr. 13 lb. Cost of sulphate per ton (exclusive of liquor)=£6 15s. Amount realised for ammoniacal liquor per ton of coal, before introduction of sulphate manufacture, 1s. 1.15d. Amount realised for sulphate of ammonia per ton of coal, 2s. 4d. The liquor as run into the first still contained 2.54 per cent. of ammonia, when

run into the second 0.589 per cent., and when taken from this latter only .068 per cent., clearly proving the advantage of using the lime in the second still. With a view to utilising the waste gases evolved in the sulphate manufacture, a sulphuric acid plant was erected at a cost of £380 for chamber and condensers and £70 for the kiln. When sulphur was used acid of 150° Tw. was produced at a cost of £3 10s. per ton, against £3 15s. for acid purchased at a distance. Now by the use of spent oxide—estimating the cost at 7d. per unit—the same acid is obtained for £2 per ton. The gain effected by this represents about 1½d. per ton of coal carbonised.—A. R. D.

*Contributions to the Chemistry of Mineral Fuels.* Boessingault. Dingl. Polyt. Journ. 331, 250, 1884. Taken from Comptes Rendus 1883, 96, 1452.

THE author has examined the bitumen from the so-called burning springs of Ho-Tsing, in the provinces of Szu-Tehnan, China, where, in a region having an area of 50 square miles, several thousand springs exist, whence proceed inflammable gases at a high velocity, accompanied by bitumen and brine. At ordinary temperatures the bitumen is in the fluid condition, but when cooled, naphthalene separates out. The solid and liquid constituents of the bitumen separated by cooling and filtration have the following composition:—

	C.	H.	O.	N.
Solid.....	82.85	13.06	4.06	0
Liquid.....	86.82	13.16	0	0.02

Samples of asphaltum respectively from Egypt (I.) and from the Dead Sea (II.) possessed the following composition:—

	I.	II.
Carbon.....	85.29	77.84
Hydrogen.....	8.24	8.93
Oxygen.....	6.22	10.53
Nitrogen.....	0.25	1.70
	100.00	100.00

An amber-like fossil resin from the alluvial regions of New Granada, found in a lump weighing about 12 kilos, at the gold-washing establishment of Giron near Bucaramanga (I.), and a fossil resin from the auriferous alluvium of the province of Antioquia (II.), gave the following results upon analysis:—

	I.	II.
Carbon.....	82.7	71.89
Hydrogen.....	10.8	6.51
Oxygen.....	6.5	21.57
Nitrogen.....	0	0.03
	100.0	100.00

Pit coal from Canoas, situated in the Cordillera range, on the plateau of Bogata, 2,800 metres above the level of the sea (I.), and coal from the province of Antioquia (II.), yielded the following analytical results:—

	I.	II.
Carbon.....	80.46	87.05
Hydrogen.....	5.13	5.00
Oxygen.....	12.50	6.56
Nitrogen.....	1.41	1.39
	100.00	100.00

Two samples of the so-called "fusain," from the mines respectively of Blanzi (I.) and Montrambert (II.), Loire, contained—

	I.	II.
Carbon.....	87.81	93.05
Hydrogen.....	3.88	3.35
Oxygen.....	7.67	3.43
Nitrogen.....	0.64	0.17
	100.00	100.00

Anthracite from Chili (I.), and from Muso, New Granada (II.)—

	I.	II.
Carbon.....	92.25	94.83
Hydrogen.....	2.27	1.27
Oxygen.....	4.94	3.16
Nitrogen.....	0.51	0.71
	100.00	100.00

W. D. B.

*Improved Means of Obtaining Salts of Ammonia from Combustible Gases.* John Addie, Glasgow. Partly communicated by James Addie, Bilbao, Spain. Eng. Pat. 3246, June 30, 1883.

By this invention the ammonia "which is contained in combustible gases, such as the gases obtained from blast furnaces, coking ovens, and gas producers, is directly converted and recovered as sulphate of ammonia by a continuous process, consisting of the following stages, viz.: (1) The combustible gases are charged or intermixed with sulphurous acid gas in sufficient quantity to combine with and fix the ammonia contained in them. (2) The gases are submitted to the action of a scrubber, or to equivalent action, to dissolve the sulphite formed. (3) The solution of sulphite of ammonia is oxidised by forcing or injecting air thereinto."

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*On the Pyridine Bases in Coal Tar.* Heinrich Goldschmidt and E. J. Constam. Berl. Ber 16, 2976.

THE existence of two isomeric picolines having been predicted by E. Jacobsen and C. L. Reimer (Berl. Ber. 16, 2604), who obtained two different products by treating the picoline prepared from coal tar with phthalic anhydride and zinc chloride, the authors give a preliminary account of their investigation of the isomeric pyridine bases in coal tar. A considerable quantity of sulphuric acid, which had been almost saturated with bases in the purification of tar, was treated with steam to remove hydrocarbons, supersaturated with caustic soda, and the bases distilled with steam. The distillate was acidified with hydrochloric acid and evaporated, but the smelly impurities could not be removed by filtration. The liberation of the bases and distillation with steam were therefore repeated, and the acidified distillate was concentrated. After filtration the clear liquid was treated with caustic soda, and the liberated bases dried with solid caustic potash. 1 kilo. of the bases was obtained from 10 litres of the raw material. The product boiled between 92° and 200°. After repeated fractionation it was found that a little of the substance came over below 100°, about one half of the whole quantity between 114° and 117° (pyridine), while above this temperature no constant boiling point was observed. Very little came over above 160°. The portion below 100° boiled constantly at 92° to 93°, and was found to be a compound of pyridine and water. The addition of solid potash caused the separation of pyridine, boiling at 114° to 115°. The platinum double salt was prepared and analysed. The hydrate of pyridine, which has the composition  $C_5H_5N + 3H_2O$ , was prepared from pyridine by the addition of one-third of its volume of water and subsequent distillation. Two fractions were obtained, one at 92° to 93°, the other at 114° to 115°. The specific gravity of the hydrate is higher than that of a simple mixture of pyridine and water. The vapour density determination showed that the hydrate is decomposed by its conversion into vapour. The authors observe that the base obtained by Fritzsche from coal tar, and which boiled at 95°, was probably not identical with the cespitin, ( $C_5H_5N$ ), discovered by Church and Owen in the distillation products of turf, but was probably the hydrate of pyridine. The portion of the mixture of bases which came over between 114° and 117° was found to be pyridine. The fractions between 130° and 140° were mixed, but the quantity was not sufficient to allow of the removal of the lutidine. The bases were oxidised, according to Weidel's method,

with potassium permanganate, and the concentrated aqueous solution of the potassium salt treated with copper acetate. After removal of the copper from the precipitated salt by means of sulphuretted hydrogen and decolorisation of the filtrate with animal charcoal, the solution on evaporation yielded colourless needles of picolinic acid, melting at 137°. The filtrate from the copper picolinate was evaporated, acidified with acetic acid, and treated at its boiling point with copper acetate, whereby a blue-green precipitate was obtained, which, after being boiled repeatedly with water, was treated with sulphuretted hydrogen. The filtrate from the copper sulphide yielded on evaporation colourless crusts, melting at 310°. They were found on analysis to consist of pyridine carbonic acid. The properties of the acid show that it was isonicotinic acid ( $\gamma$ -pyridine carbonic acid) and therefore either  $\gamma$ -picoline, which has not yet been prepared, or lutidine must have been present among the bases. The quantity of picolinic acid was far greater than that of isonicotinic acid. These results show that orthomethylpyridine is the chief constituent of the mixture of picolines obtained from coal tar.—S. Y.

*On the Thiophene and Pyrrol Groups.* Victor Meyer.  
Berl. Ber. 16, 2968.

THE great similarity exhibited by thiophene, and the compounds already prepared from it, to benzene and its derivatives, led the author to the conclusion that thiophene differs from benzene only in the substitution of one of the acetylene groups forming the benzene ring by an atom of sulphur. This conclusion has so far been verified. Thiophene sulphonic acid ( $C_4H_3S-SO_3H$ ) and thiophenic acid ( $C_4H_3S.COOH$ ) prepared by the author and Herr Kreis, resemble benzene sulphonic acid and benzoic acid so closely that they are hardly to be distinguished except by analysis, or by the isatin test described below. The following are some of the results obtained by the author and his students—*Simple Condensation Products of Thiophene*: Thiophene forms condensation products like the aromatic hydrocarbons, in the manner described by Baeyer, and by Friedel and Crafts. Thus, with chloral in presence of glacial acetic acid and sulphuric acid, the substance—

is formed, and it is decomposed by alcoholic potash in the same way as the benzene derivative. Bromal gives a similar product. The resemblance of dithienyl methane prepared from methylal to diphenyl methane extends even to its characteristic odour of oranges. It is, however, easily distinguished by its higher melting point and by its reaction with isatin. This substance, in presence of sulphuric acid, has no action on dithienyl methane in the cold; but on heating, the beautiful indophenine reaction is at once observed. The reaction is characteristic of almost all the derivatives of thiophene—thus thiophene sulphonic acid and thiophenic acid remain unaltered in the cold, but produce the deep blue colouration when warmed with isatin and sulphuric acid. Since the term thiophenyl is already employed for phenyl compounds containing sulphur, the author proposes the name thiényl for the radical  $C_4H_3S$ , which stands to thiophene in the same relation as phenyl to benzene. Care must be taken in testing thiophene according to Friedel and Crafts' reaction, not to employ an excess of aluminium chloride, or the thiophene may be decomposed with liberation of sulphuretted hydrogen. Good results are obtained with benzyl chloride, benzoyl chloride, and phthalyl chloride. Benzoyl chloride, treated with thiophene and a small quantity of aluminium chloride, yields phenylthienylketone ( $C_6H_5.CO.C_4H_3S$ ), analogous to benzophenone. The ketone gives with hydroxylamine the isonitroso compound  $C_6H_5.C(NO.H).C_4H_3S$ , and this, when heated with soda-lime, is decomposed with formation of benzoic acid and thiophene. The ketone gives a blue coloration when heated with isatin and sulphuric acid. *Homologues of Thiophene*: It is difficult to prepare monobromothiophene, for by the bromination of thiophene the dibromo compound is formed in larger

quantity, and hence the preparation of the next homologue of thiophene has not been carried out by means of this compound. But the author was led to believe that methylthiophene was present in the toluene obtained from tar; and at his request Dr. Caro, of Ludwigshafen, converted the sulphuric acid extract from 2,000 kilos. of toluene into the sulphonic acid, and then eliminated the sulphonic group by distilling the lead salt with sal-ammoniac. By this means an oil was obtained which, after rectification, boiled constantly at 110°. It contained 5 per cent. of sulphur, and appeared to consist of 15 per cent. of methylthiophene, and 85 per cent. of toluene. The product, when tested by Laubenheimer's reaction, gave far more characteristic results than ordinary toluene. Methylthiophene itself has not been isolated, but the dibromo compound

has been prepared in a state of purity. It boils without decomposition at 227° to 229°. The xylene and cumene obtained from coal tar also exhibit Laubenheimer's reaction, and therefore probably contain the corresponding homologues of thiophene. *Thiophene Sulphonic Acid*: A number of salts have been prepared, and also the chloride, amide, anilide, and the ethyl ether, and the sulphonic acid  $C_4H_3S.SO_3H$ , and mercaptan  $C_4H_3S-SH$  are in course of preparation. The phenol  $C_4H_3S-OH$  has not been obtained. *Colouring Matters from Thiophene*—(a) *Thiophene and Phenylglyoxylic Acid*: The formation of the violet-red colouring matters described by Claisen, by the action of phenylglyoxylic acid and its derivatives on benzene, is due to the presence of thiophene in that substance. Solutions of phenylglyoxylic acid and thiophene in glacial acetic acid were mixed and treated cautiously with concentrated sulphuric acid, and the product was poured after some hours into water, when a beautiful red flocculent precipitate was formed, which, after being washed and dried, was found, on analysis, to possess the composition  $C_{12}H_8SO_2$ . Its formation is probably represented by the equation—

It dissolves in chloroform with a carmine, and in sulphuric acid with a deep violet-red colour. The colour of the latter solution changes suddenly on warming into a pure blue. (b) *Phenanthrene Quinone and Methyl Thiophene*: A mixture of the acetic acid solutions of phenanthrene quinone and the crude methyl thiophene obtained from toluene, yields a colouring matter which dissolves in alcohol and ether with a deep violet colour. The determination of the sulphur in the product agrees with the formula  $C_{19}H_{12}SO$ . When distilled with zinc dust a crystalline hydrocarbon is formed. Hence thiophene may be found useful in the production of the higher hydrocarbons. (c) *Phenanthrene Quinone and Thiophene*: Laubenheimer, who described the characteristic colour reactions of xylene and toluene with phenanthrene quinone, failed to observe the corresponding reaction with benzene, owing to the insolubility of the colouring matter in ether. It dissolves, however, in chloroform, forming an emerald-green solution. The colouring matter was prepared in quantity by the action of phenanthrene quinone on thiophene. Many other ketones give colouring matters with thiophene. According to the author those ketones which contain only carbon, hydrogen, and oxygen form colouring matters with thiophene when they contain the group  $CO-CO$ . On the other hand, simple ketones, and double ones, in which the carbon atoms of the two carboxyl groups are not directly combined, give no colouring matters. The intensity of the colour depends obviously on the nature of the molecule containing the group  $CO-CO$ . If it belongs to the aromatic or uric acid groups the colour is deep and beautiful, if to the fatty group the colour is weak and dull. Thus, pyruvic acid and thiophene give a dull violet colouring matter. Many aldehydes also yield colouring matters with thiophene, but they appear to have a more complex constitution than those formed from the double ketones. *Nitrogenous Colouring Matters from Tar*: The author obtained a tar oil from Dr. Häussermann, in Griesheim a. M.,

which boiled between  $90^{\circ}$  and  $109^{\circ}$ , and consisted chiefly of benzene and toluene, together with hydrocarbons of the fatty group and considerable quantities of pyridine bases which could readily be extracted by dilute acids. When this oil was treated with an aqueous solution of isatin and dilute sulphuric acid, a deep blue precipitate resembling indigo was formed. After treatment with a dilute acid, however, the oil gave no such precipitate, nor did the bases liberated from the acid extract. It was suggested by Dr. Caro that the reaction was caused by the presence of pyrrol in the oil, and this was found to be the case. When pyrrol is treated with isatin and dilute sulphuric acid the same colouring matter is formed, the yield amounting to 120 per cent. of the isatin employed. The substance is evidently formed by the combination of isatin and pyrrol, with elimination of water. The analogy of pyrrol, for which the author had already suggested the constitution—

with thiophene—

is shown by the fact that colouring matters are formed by the action on pyrrol, in presence of dilute acids, of the same substances which give colouring matters with thiophene. With the exception, however, of the isatin compound, the pyrrol colouring matters are unstable, and in this respect resemble the colouring matters of flowers. The analogy of furfuran—

with thiophene has been pointed out previously by the author. It thus appears that of the three acetylene groups forming the benzene ring one may be replaced by S, O or NH, without destroying the characteristic properties of benzene.—S. Y.

#### On Acridine. C. Graebe. Ber. 16, 2828.

THE interesting researches of Bernthsen and Bender (this Journal III., 1, 24) having shown that the composition of acridine is represented by the formula  $\text{C}_{13}\text{H}_9\text{N}$ , and not  $\text{C}_{12}\text{H}_9\text{N}$ , the author has again investigated this subject, as the values which were obtained by Caro and Graebe in their former researches on acridine extracted from coal-tar have agreed more closely with the formula  $\text{C}_{12}\text{H}_9\text{N}$ . The author found that the composition of crystallised acridine when fused is represented by the formula  $\text{C}_{12}\text{H}_9\text{N}$ , whilst acridine dried at  $100^{\circ}$  gave numbers agreeing with the formula  $\text{C}_{13}\text{H}_9\text{N}$ . This difference he attributes to the fact that acridine, especially during its fusion, absorbs small quantities of oxygen from the atmosphere, so that on analysis low results are obtained as regards the carbon. This difference being most noticeable in the case of the platinum-chloride, the author has carefully prepared this salt in a pure form. Analysis gave numbers agreeing more satisfactorily with the formula  $\text{C}_{13}\text{H}_9\text{N}$ . These results with the facts already established by Riedel, and Bernthsen, and Bender, leave no doubt as to the composition of acridine. The author has again prepared acridine sulphate, and studied its properties. It forms an insoluble salt, which can be dried at  $100^{\circ}$  without decomposition. However, on continued boiling with water sulphurous anhydride and acridine are

volatilised. Acridine-octohydride ( $\text{C}_{13}\text{H}_{17}\text{N}$ ) is prepared by mixing 5grms. of acridine, or 6grms. of the hydrochloride with 2grms. of amorphous phosphorus and 6grms. to 7grms. hydriodic acid (boiling point  $127^{\circ}$ ), and heating the mixture at  $220^{\circ}$  to  $230^{\circ}$  for 6 or 7 hours. The base crystallises from alcohol in colourless laminae, or long plates. It does not yield coloured or fluorescent solutions. Melting point,  $84^{\circ}$ ; boiling point,  $320^{\circ}$ . The hydrochloride crystallises in colourless plates, which are readily soluble in hot water. On heating the base with acetic anhydride and benzoyl-chloride the acetyl and benzoyl derivatives are produced. Methyl iodide forms methyl acridine octohydride.—D. B.

#### New Method of the Formation of Acridine. O. Fischer and G. Koerner. Berl. Ber. 17, 101.

IN attempting to prepare triphenylparaleucaniline by the action of chloroform on diphenylamine, the authors obtained instead considerable quantities of acridine. One part of chloroform, one part of diphenylamine, one part of zinc chloride, and about half a part of zinc oxide are heated to  $200^{\circ}$  or  $210^{\circ}$ , under pressure, for seven or eight hours. The contents of the tube are boiled with concentrated hydrochloric acid, the filtered solution poured into water, again filtered, and the acridine precipitated by an alkali, after which it is recrystallised from hot water. This process, which gives a better yield than that with formic acid and diphenylamine, recently described by Bernthsen and Bender (*Berl. Ber.* 16, 1802), especially if aluminium chloride be substituted for zinc chloride, is explained by the following equation:—

A. S.

*Erratum:* III. [1] 24 January. Hydroacridine should be

#### On the Examination of Petroleum. Dingl. Polyt. Jour. 250, [4], 169-172.

ACCORDING to F. Beilstein, the forms of apparatus recommended by Abel, Engler and others, for testing the flashing point of petroleum, with due care give good results, but it is necessary that the construction of the apparatus should be always the same, or different experiments will show different values. Two of Engler's testers, apparently of the same capacity, gave a difference of  $2^{\circ}$  for one and the same oil, because the marks to which the sample was filled were not of the same height, and therefore left a different air layer above the oil. According to Liebermann and Stoddard the results depend upon the size and kind of flame employed for igniting the vapour. Should the length of the apparatus be from five to seven times its breadth, the results are concordant, but if this proportion be exceeded, higher results will be obtained. If the apparatus have the right height, it is a matter of indifference whether it be filled one-quarter or two-thirds full of oil, but the quantity of air passed must not be too small. The length of time the ignition flame is held to the opening of the apparatus is also important. Beilstein recommends an apparatus consisting of a glass cylinder 35m.m. in diameter and 175m.m. in length, with two marks, one of which is 60m.m. from the bottom, the other 70m.m. The oil is poured in up to the first mark. Air is conducted from a gasometer by means of an indiarubber tube attached to a fine glass tube, terminating in a rose perforated with fine holes. The bulb of the thermometer is arranged about the middle of the oil. The apparatus is put into a water-bath, of which the temperature is increased one degree every two to three minutes. Each time the temperature of the oil shows a further rise of one degree, air is passed through for five seconds, and so quickly that a froth is raised in the upper part of the apparatus, while at the same time a flame is held at the mouth, and the temperature at which the vapour ignites is noted. The first result is only approximate. The oil is replaced by a fresh quantity, and the observations commenced at about that temperature which was found to be the flashing-point in the preceding trial. In this way observations can be made

to 5° C. This apparatus gives a flash-point about five degrees higher than that of Engler. If the oil is so heated that the temperature of the water-bath is one degree higher than that of the oil, single observations vary about 25° C. Other forms of apparatus have not hitherto allowed of this degree of accuracy. In the preceding method there is ascertained the temperature at which the oil is dangerous for burning, but nothing is learnt about its capability of burning. For the latter purpose the distillation of the oil is requisite. The distillation is conducted in the following way: 200 grammes of the sample are placed in a weighed retort provided with a Glinzky's dephlegmator, to which is attached a tube about 0.75m. long without any condenser. The distillation is so regulated that about 2 grammes of the distillate shall pass over into the weighed receiver every minute. The distillates below 150° C. and between 150° C. and 270° C. are collected separately and weighed. The distillation is stopped at 270° C., the retort reweighed, and the amount of residue thus obtained. American petroleum gives 5 per cent. of a light oil boiling below 150° C. and less than 15 per cent. of a heavy oil boiling above 270° C. Such petroleum burns excellently in all kinds of lamps. According to Beilstein, petroleum which contains not more than 5 per cent. of light oil is quite free from danger. Mendelejeff states that fractions of petroleum from Baku, boiling between 15° and 150° have a density not always corresponding to the rise of temperature. The fraction boiling between 29° and 30° has a specific gravity of .626; that at 50° of .675; at 62° of .672; at 80° of .7483; at 90° of .7337; at 100° of .7659; at 140° of .7807; and at 150° of .7908. The coefficients of variations in specific gravity are in like manner related to the temperature. For the fraction boiling at 80° it is -.00093; at 86° -.00086; at 90° -.00084; at 98° -.00086; at 100° -.00088; at 110° -.00081; and at 114° -.00079. At higher temperatures these fractions gradually become less. According to Mendelejeff, petroleum from Baku contains the same kind of hydrocarbons as the American oil, but the low boiling fractions contain a small quantity of a hydrocarbon boiling at 55°, which has a higher density than hexane. The bulk of the hydrocarbons of the oil from Baku corresponds to the formula  $C_nH_{2n}$ . The behaviour of these hydrocarbons with bromine, nitric acid, potassium permanganate, and mercuric chloride, makes it probable that hydrocarbons of the acetylene series are also present. For the detection of aromatic hydrocarbons in petroleum products, G. Gustavson adds 10 to 15 grms. of aluminium to 1 or 2 grms. of bromine, and to the aluminium bromide thus formed 1 or 2 c.c. of the sample. The mixture is poured upon a watch-glass, and cautiously evaporated, when the needle-shaped crystals remain if the sample contained benzene or toluene. Alex. Ehrenberg, of Dresden, has constructed an apparatus for testing the flashing points of oils. It consists of two tubes joined together, a piston, a thermometer and small tube leading to the ignition flame. The apparatus is filled with the oil to be tested, and the temperature regulated by means of a water-bath. At intervals the piston is pushed down, and the gas given off by the oil is thus brought into contact with the flame. Upon raising the piston the observation can be repeated until the flashing point is found. The apparatus can be made of either glass or metal.—A. H. A.

#### Action of Phosphorus Trisulphide on Phenol and Cresol.

A. Geuther. *Annalen* 221, 55.

KEKULÉ and SZUCH have shown that by the action of phosphorus pentasulphide on phenol, besides phenylsulphhydrate, phenyl sulphide, and a high boiling product, a small amount of benzene is formed. As the formation of benzene from phenol depends on a reduction process, which, if brought about by pure phosphorus pentasulphide, could not be easily explained, it was thought that the pentasulphide must have contained some trisulphide, and that the reduction was due to the presence of this substance. On investigation this was found to be the case. 60 grms. of finely-pulverised phosphorus trisulphide and 10 grms. of phenol were heated for

three to four hours in a retort provided with a reflux apparatus. The volatile products were then expelled by heat. A small quantity of undecomposed solid phosphorus trisulphide being carried over mechanically was removed by filtration. The filtrate on fractional distillation was divided into two parts, the first distilling under 100° and the second boiling over 360°. Phenylsulphide, which boils at 250°, and phenylsulphhydrate, boiling at 165°, were present only in small quantities. The weight of the portion boiling under 100° was 16 grms. It was rectified, when it showed a constant boiling point of 81°. It was found to resemble benzene in properties and chemical constitution. The fraction distilling above 360° contained only traces of sulphur. Its solution in nitric acid liberated phosphoric anhydride very freely, a reaction indicative of the presence of phenylethylphosphoric acid. By taking into consideration the fact that almost the whole of the sulphur escapes in the form of sulphuretted hydrogen, and that the resulting benzene corresponds to one-fourth the phenol used, it may be assumed that the equation which illustrates this reaction is as follows:—

The formation of phenylsulphide and phenylsulphhydrate is explained by the following equations:—

whilst the change which takes place when phosphorus pentasulphide is used would probably be illustrated by the equation

The reduction of phenol to benzene by means of phosphorus trisulphide having proved a success, it was thought that this sulphide would act in an identical manner on the homologues of phenol. On subjecting cresol to the action of phosphorus trisulphide, and proceeding in the above-described manner, it was possible to obtain toluene having a boiling point of 110°. Besides the fraction distilling above 360° and probably consisting of tolylethylphosphoric acid, an intermediate product boiling at 185° to 195° was obtained, which appeared to be a mixture of tolylsulphhydrate and undecomposed cresol. Toluylsulphide was not formed. These results show that it is possible to abstract oxygen from phenols by the aid of phosphorus trisulphide and convert them into the corresponding hydrocarbons.—D. B.

#### Products of the Destructive Distillation of Wood at Low Temperatures. C. F. Mabery. *Amer. Chem. Jour.* 5, 256.

THE author has examined fractions of crude wood spirit, (a) being taken at the commencement of the distillation; (b) after several hundred gallons had distilled over; and (c) when the distillation of methyl-alcohol had made considerable progress. (a) showed a high percentage of ethylaldehyde; (a) and (b) methylacetate; and (c) methylalcohol. Dimethylacetate and small quantities of acetone were also present.—D. B.

#### Picamar. By G. Niederist. *Monatsh. Chem.* 4, 487.

THE author came into possession of an original specimen of picamar prepared by Reichenbach himself, which was employed in the experiments described in this paper. The main result of the investigation was to establish the identity of this compound with the dimethylpropylpyrogallate obtained by Hofmann from beechwood tar, (*Ber.* 8, 66, and 11, 329). The statements of Reichenbach in regard to the properties of the substance are fully confirmed by the author. The following compounds are also described: Potassium picamar,  $C_{11}H_{15}O_5K$ . This was prepared according to Reichenbach, and obtained in the form of pearly plates. Acetyl picamar,  $C_{11}H_{15}(C_2H_3O)_3$ , by heating picamar for several hours with acetic anhydride in excess. It crystallises from alcohol in shining prisms (melting point 86-87°). Dibromacetyl picamar,  $C_{11}H_{13}Br_2(C_2H_3O)_3$ , crystallises from alcohol in colourless shining plates.—C. F. C.

*Improvements in Processes for Bleaching Ozokerit and other Solid Hydrocarbons, and for Rendering them Available as Substitutes for Wax.* J. Imray, London. Communicated by J. C. O. Chemin, Paris. Eng. Pat. 3435, July 12, 1883.

"CRUDE ozokerit is first melted in water kept at a temperature of 70° C., and the earthy and other solid impurities being allowed to settle, the melted matter is decanted, and solidifies in a condition fit to be treated by the following operations. First it is melted by superheated steam, and from 5 to 15 per cent. of flowers of sulphur being added, the material is distilled. The distillation, which is not fractional, gives a product, yellow, homogeneous, without fluorescence or dichroism. This being slowly cooled crystallises, the product being from 92 to 95 per cent. of the total quantity treated. The second operation may be conducted in either of two ways, either by subjecting cakes of the distillate to pressure, the plates of the press being kept at a temperature of 35° to 50° C., thus expressing the oils and hydrocarbons fusible at low temperatures, or by reducing the distillate to powder, and subjecting it to a shower of water at a temperature of 45° to 60° C., so as to wash away the oils and fusible hydrocarbons. Instead of water, amyl alcohol or other solvent of hydrocarbon oils may be employed at ordinary temperatures. The third operation consists in melting the product of the second at 60° or 70° C., and mixing intimately with it about 20 per cent. of amyl alcohol, then casting the whole into moulds. The cakes, after being subjected to pressure, are melted and digested for about four hours in agitation with animal charcoal, and the liquid is filtered through animal charcoal. On cooling, the product, amounting to about 80 per cent. of the matter treated, is white, hard, and sonorous. The liquids resulting from the third operation, or from the washing by alcoholic solvents, are distilled, so as to recover the alcohol and solvents, and the residue is mixed with the crude material to be subsequently treated. From 20 to 30 parts of residue from treatment of petroleum and naphtha may be mixed with 70 to 80 parts of crude ozokerit. A similar treatment is applicable to solid hydrocarbons generally, such as residues from petroleum, naphtha, pitch and tar, schist oils, and the like."

*Improvements in or Relating to the Treatment of the Products of Combustion or Destructive Distillation of Coal or other Fuel containing Nitrogen for the Purpose of Utilising the Ammonia contained therein.* J. H. Darby, Brymbo. Eng. Pat. 3084, June 21, 1883. Void, final specification not filed.

By this invention furnace or other gases containing ammonia are to be passed through "any ordinary coke tower or scrubber," into the top of which is fed "water-spray or weak liquor" steam, "sulphurous anhydride, and gaseous oxides of nitrogen" being introduced into the flue conveying the gases to the foot of such tower, at "a sufficient distance from the tower to enable the gases to mix before entering" it. The liquid running from the bottom of the tower is thus to be solution of ammonium sulphate, which solution may be pumped to the top of the tower and passed through it a sufficient number of times to render it at last highly concentrated.

#### IV.—COLOURING MATTERS AND DYES.

*The Indulins.* Otto N. Witt. Berl. Ber. 17, 74.

THE author describes a new method of preparing the indulins. When carried out in the usual way from amidoazobenzol and aniline, the preparation of the indulins is attended with evolution of ammonia, and the formation of complicated by-products. If, however, the phenyl-amidoazobenzol, previously described by the author, be heated with aniline hydrochloride, no trace of ammonia or ammonium salts is formed, and it appears also that the formation of complicated by-products is avoided. This method of preparation is more rapid and easy than the older one. The formation of the substance is explained

as being due to a breaking-up and subsequent reduction of the azo group by the hydrogen of the aniline, which, in its turn, unites with the amidodiphenylamine (phenylparaphenylenediamine) formed by the reduction of the azo body, thus giving indulin. From this, an analogy with the colouring matters of the tolylene blue series and the saffranine group is apparent, these, like the indulins, being obtained by the abstraction of hydrogen from a mixture of a monamine and a paradiamine. The higher homologues behave in a similar manner to phenylamidoazobenzol. The product from diazoparatoluid and diaphenylamine forms yellow plates, melting at 109° to 110°, and soluble with a green colour in concentrated sulphuric acid. The corresponding derivative of metaxylydine (1, 2, 4) forms bright golden scales which melt at 142° to 143° and dissolve in concentrated sulphuric acid with a yellow colour. If in these compounds diphenylamine be replaced by other secondary aromatic amines, amidoazo bodies are obtained, which, without any difficulty, yield whole series of new colouring matters resembling indulin, when treated with the salts of primary bases.—A. S.

*On some Derivatives of  $\alpha$ - and  $\beta$ -Naphthol.* Emil Friedländer. Berl. Ber. 16, 2075.

By heating the naphthols with aniline or ortho- or para-toluidine in presence of calcium chloride to a temperature of 230° to 250°, secondary amines are formed in abundance. As a rule, for one molecule  $\alpha$ - or  $\beta$ -naphthol two molecules of base and one molecule of calcium chloride were used. In the absence of calcium chloride the yield of secondary amines was notably smaller, generally only one half. Phenyl- $\beta$ -naphthylamine crystallises in tufts of white needles, which melt at 108°. Para-tolyl- $\beta$ -naphthylamine crystallises from warm spirit of wine in white shining scales, melting at 102° to 103°. With acetic anhydride yields the crystalline compound—

whilst by the action of benzoyl chloride the compound—

is obtained. Para-tolyl- $\beta$ -naphthylamine gives with bromine silver-white needles of the compound—

which melts at 168° to 169°. Phenyl- $\alpha$ -naphthylamine, previously prepared from  $\alpha$ -naphthylamine and aniline hydrochloride, forms white crystals, melting at 60°. Paratolyl- $\alpha$ -naphthylamine forms white crystalline tufts which melt at 88.5° to 79°. Orthotolyl- $\beta$ -naphthylamine remains persistently as an oil, but crystallises from petroleum spirit in bright scales melting at 95° to 96°. With picric acid it gives the compound—

which crystallises in reddish brown needles, and is only moderately soluble. Benzoyl chloride and orthotolyl- $\beta$ -naphthylamine yield the compound—

melting at 117° to 118°. Orthotolyl- $\alpha$ -naphthylamine forms small white shining needles melting at 94° to 95°. The data contained in this paper show, as already indicated by previous investigations, that  $\beta$ -naphthol enters into reactions with considerably greater facility than its  $\alpha$ -isomer. All the amines described gave colour reactions with nitric acid, as well as with potassium dichromate and sulphuric acid, in the case of the  $\beta$ -naphthyl compounds varying from yellow to brown, with the  $\alpha$  compounds green and greenish blue. The phenyl-, paratolyl-, and orthotolyl- $\beta$ -naphthylamines were decomposed by concentrated hydrochloric acid at a temperature of 240°;  $\beta$ -naphthol and aniline or a toluidine being formed, e.g.—

The author has been unable to confirm the statement that naphthalene and naphthylamine are formed by the action of concentrated hydrochloric acid on phenyl- $\beta$ -naphthylamine. A. S.

*Action of Aniline on Resorcinol and Quinol.* A. Calm.  
Ber. 16, 2786-2814.

On heating resorcinol or quinol with calcium chloride and aniline hydrochloride to 250°, or with aniline hydrochloride to 300°, metoxydiphenylamine and paroxydiphenylamine are formed respectively, the yield being very satisfactory. It is of special interest to find that resorcinol and quinol when heated with aniline *per se* react in an analogous manner. The reaction, however, goes beyond the monoxy bodies, though only in a small measure, and causes the formation of diphenylmeta- and diphenylpara-phenylenediamines. The yield of metoxydiphenylamine under normal conditions amounts to 70 to 80 per cent.; that in the case of the isomeric para- compound to 80 to 90 per cent. of the theoretical quantity. When the preparation of the diphenylated phenylenediamines is sought for it is best to use a mixture of zinc chloride and aniline hydrochloride with an excess of calcium chloride and aniline hydrochloride. The reaction takes place at 200° to 210°. The yield is high, although a small amount of the monoxy body is still present. The following equations explain the changes which occur when resorcinol and quinol are acted upon by aniline:—

The primary derivatives are distinguished from the secondary by their solubility in dilute alkalis and acids. They are precipitated from the former solutions by acetic acid, and from the latter by acetates. The two oxydiphenylamines can be distilled with ease by means of superheated steam, whilst the distillation of the phenylated diamido compounds requires a very high temperature. Zinc dust reduces the oxydiphenylamines at a moderate red heat, diphenylamine being formed besides aniline. *Metoxydiphenylamine*: White pearly laminae. Melting point, 81·5° to 82°. It is soluble in boiling water, readily soluble in alcohol and benzene. The following derivatives have been prepared:—

The hydrochloride  $\text{C}_{12}\text{H}_{11}\text{NO} \cdot \text{HCl}$

The sulphate  $(\text{C}_{12}\text{H}_{11}\text{NO})_2\text{H}_2\text{SO}_4$

The barium salt  $(\text{C}_{12}\text{H}_{11}\text{NO})_2\text{Ba} + 5\text{H}_2\text{O}$

The hydrochloride and sulphate form needles. Both are decomposed by water. The barium compound crystallises in white laminae resembling benzidine in lustre. *Diphenylmetaphenylenediamine*: Colourless flattened needles. Melting point, 95°. Is sparingly soluble in cold alcohol; readily soluble in hot alcohol, cold benzene, and ether. The following derivatives were prepared:—

The hydrochloride  $\text{C}_{12}\text{H}_9(\text{NHC}_6\text{H}_5)_2 \cdot \text{HCl}$

Acetyl compound  $\text{C}_{12}\text{H}_9(\text{NC}_6\text{H}_5)_2 \cdot \text{C}_2\text{H}_3\text{O}_2$ . M. pt. 163°

Benzoyl compound  $\text{C}_{12}\text{H}_9(\text{NC}_6\text{H}_5)_2 \cdot \text{C}_7\text{H}_5\text{O}_2$ . M. pt. 183°

Nitroso compound  $\text{C}_{12}\text{H}_9(\text{NC}_6\text{H}_5)_2 \cdot \text{NO}$ . M. pt. 102°

The hydrochloride crystallises in fine needles, and is decomposed like the corresponding compound of the monoxydiphenylamine. The acetyl and benzoyl derivatives form colourless crystals. The nitroso body crystallises in yellow needles. By treating a small amount of the nitroso compound with concentrated sulphuric acid a deep violet-blue colouration is resulted. *Paroxydiphenylamine*: Forms spangles or laminae. Melting point, 70°. Is sparingly soluble in petroleum spirit and cold water; dissolves in hot water and cold alcohol, and is readily soluble in hot alcohol. The hydrochloride  $\text{C}_{12}\text{H}_{11}\text{NO} \cdot \text{HCl}$ , crystallises in white needles, which water decomposes. *Diphenylparaphenylenediamine*: Crystallises in colourless lustrous laminae. Melting point, 152°. Sparingly soluble in cold alcohol, more soluble in hot alcohol and cold benzene, readily soluble in boiling benzene, ether, and chloroform. Derivatives prepared: The hydrochloride and the acetyl, benzoyl, and nitroso compounds. These substances agree in constitution with the analogous derivatives of diphenylmetaphenylenediamine. They

crystallise with ease, but are more difficultly soluble. The melting points of the acetyl and benzoyl derivatives are 191·7° and 218·5° respectively. The solution of diphenylparaphenylenediamine in concentrated sulphuric acid forms with nitric acid or saltpetre a deep cherry to fuchsine-red colour. On heating paroxydiphenylamine with calcium chloride, zinc chloride and paratoluidine diparatolylparaphenylenediamine is produced, besides diphenylparaphenylenediamine. This body, which forms well-defined crystals, has been prepared by the author from quinol and paratoluidine.

*On some Derivatives of Quinone.* R. Nietzki, Ber.  
Deutsch. Chem. Ges. 1883, 2092.

In order to produce nitranilic acid a mixture of 5 parts of fuming nitric acid with an equal quantity of concentrated sulphuric acid is cooled to about 8°, and to this is to be added, little by little, so that the temperature may never rise above - 3°, 1 part of finely-powdered diacetylquinol. The mixture, which towards the end of the operation becomes pasty with deposited crystals, is maintained at a low temperature until a small portion, removed for the purpose, yields a clear solution with much iced water, and gives no violet, but only a dirty brown colour with an excess of alkali. The product may be thrown upon pieces of ice, the crystals remaining for the most part undissolved. These crystals consist of nitranilic acid, which is but slightly soluble in the acid solution, but is readily decomposed by it in a short space of time. They yield a precipitate of stable potassium nitranilate with a solution of potassium chloride. It is best, therefore, to convert the acid at once into the potassium salt. To a quantity of caustic potash solution, somewhat in excess of that required to neutralise the total acid in the solution to be treated, are added a few pieces of ice, and, gradually and with constant stirring, the nitranilic acid solution. After some 12 hours the precipitated potassium salt is filtered, and may be re-purified by recrystallisation from hot water containing potassium hydroxide. In this way some 60 per cent. of the diacetylquinol is converted into potassium nitranilate. Nitranilic acid cannot thus be prepared from quinone. The potassium salt dissolves in a solution of stannous chloride, acidified strongly with hydrochloric acid, yielding after a few hours sparkling violet needles of  $\text{C}_6(\text{OH})_4\text{N}(\text{H})_2 \cdot \text{NO}_2$ —W. G. M.

*On Chrysaniline.* O. Fischer and G. Körner. Berl.  
Ber. 17, 203.

THIS beautiful colouring matter has been but little investigated since the publication of Hofmann's researches in 1862 and 1869, and on account of its costliness it has not come into very general use. It occurs, together, probably, with its homologues, in company with fuchsin, and like this substance it forms a diazo compound. About two years ago, Claus observed that when chrysaniline is heated with hydrochloric acid to 160° to 180°, ammonium chloride, and a new compound, chrysophenol, derived from chrysaniline by the replacement of an amido group by hydroxyl, are formed. The striking resemblance between chrysaniline and flavaniline, as regards their fluorescence, stability, and behaviour towards fibres, made it probable that chrysaniline, like flavaniline, might be regarded as a derivative of quinoline. By the oxidation of chrysaniline Fischer obtained no oxy-acid of the quinoline or pyridine group; but chrysophenol, under the same conditions, yielded a crystalline acid which, when distilled with calcium hydrate, possessed the characteristic odour of the pyridine bases. The authors have now succeeded in proving that chrysaniline is diamidophenylacridine, both by the preparation of phenylacridine from chrysaniline and by a new synthesis of the colouring matter. Crude chrysaniline was boiled with benzene, filtered, and allowed to crystallise, and the pure substance was obtained by recrystallising the benzene compound from dilute alcohol. It was then converted into chrysophenol by heating with 3 to 4 parts of concentrated hydrochloric acid under pressure at 180°. The resulting product was dissolved in water, and poured

into very dilute caustic soda, when the phenol was dissolved, while the unaltered chrysianiline remained behind. The phenol was then precipitated by careful neutralisation with hydrochloric acid. It forms difficultly soluble salts with sulphuric and hydrochloric acids. The hydrochloride was recrystallised from hot water, and the phenol liberated by addition of soda. The composition of the substance was found on analysis to be either  $C_{19}H_{15}N_3O$  or  $C_{20}H_{17}N_3O$ , and its formation is thus represented:—

Phenylacridine was prepared from chrysianiline in the same way that E. and O. Fischer obtained triphenylmethane from paraleucaniline, and the composition of chrysianiline was therefore proved to be  $C_{19}H_{15}N_3$ . 10 grms. of crude chrysianiline were dissolved in 50 grms. of concentrated sulphuric acid and 4 grms. to 5 grms. of water, and nitrous acid was passed into the well-cooled solution. After removal of the excess of nitrous acid by means of a current of air, the diazo compound was poured in small quantities into 600 grms. of boiling absolute alcohol, and the greater part of the alcohol removed by distillation. The smeary impurities were precipitated with water, and the acid solution treated with excess of alkali. The mixture was then heated in an oil-bath to  $200^\circ$ , and a current of steam passed into it, the temperature gradually rising to  $250^\circ$ . A thick yellow oil came slowly over and solidified in the condenser. After recrystallisation it melted at  $181^\circ$ , and was found to be identical with the phenylacridine described by Bernthsen and Bender (*Berl. Ber.* 16, 1809). On analysis the composition of the substance was found to be  $C_{19}H_{13}N_3$ . The formation of chrysianiline in the preparation of fuchsin may be explained in one of three ways: (1) The paramidobenzaldehyde formed by the oxidation of paratoluidine may unite with two molecules of aniline to form the two isomeric compounds paraleucaniline and ortho-diparatramidotriphenylmethane, thus:—

The latter compound would then yield chrysianiline on further oxidation. (2) Orthotoluidine may unite with two molecules of aniline, thus:—

(3) The chrysianiline molecule may be formed by the action of amido-diphenylamine on amido-benzoic acid, just as phenylacridine is formed from diphenylamine and benzoic acid. The second explanation is the most probable, for the authors have succeeded in preparing chrysianiline by an analogous process. Renout prepared a substance which he considered to be orthodiparatramidotriphenylamine by the action of orthonitrobenzaldehyde on aniline (*Berl. Ber.* 16, 1304); and he obtained a brown colouring matter by its oxidation with arsenic acid at  $150^\circ$ . The authors find that at  $180^\circ$  to  $200^\circ$  chrysianiline is formed. The fused mass was boiled with water, and the bases precipitated with an alkali, and extracted with ether. On evaporating the ether, a yellow crystalline mass was obtained, which, after recrystallisation from benzene, yielded the benzene compound of chrysianiline. Assuming the correctness of Bernthsen and Bender's formula for phenylacridine, the formation of chrysianiline must be represented thus:—

*Improvements in the Treatment of Indigo for Use in Dyeing and Printing.* William Brookes, Chancery Lane. A communication from Thomas Holliday (Read, Holliday, and Son), Roule, Seine Inférieure, France. Eng. Pat. 2486, May 18, 1883.

THE process herein described economises both the alkali and the sulphurous acid contained in the melt resulting from the fusion of sulphonic acids with caustic alkali in the manufacture of artificial alizarin, the naphthols, and resorcinol. The solution of the melt is saturated with sulphurous acid, the hydroxy compound removed by filtration, and the filtrate, saturated with sulphurous acid, is used for reducing indigo to indigo white, by the addition of zinc dust and lime in the usual way.—R. M.

*An Improved Manufacture of Colouring Matter.* Charles Denton Abel, Chancery Lane. A communication from Messrs. Durand and Inguenin, Bâle, Switzerland. Eng. Pat. 2391, May 24, 1883. Provisional protection only.

ALPHA-NAPHTHOL is converted into its disulphonic acid by heating with five parts monohydrated sulphuric acid and two parts vitreous phosphoric acid to  $100^\circ$  C. for five hours. The product is dissolved in water and lime, the filtrate being then acidulated and treated with enough sodium nitrite to convert the sulphonic acid into the nitroso-disulphonic acid,  $C_{10}H_7(HSO_3)_2NO.HO$ . The latter is oxidised by nitric acid at the temperature of the water-bath into the nitro-disulphonic acid, which serves as a yellow dyestuff.—R. M.

*A Process of Transforming Naphthalene-disulphonic Acids into Amidonaphthalene-disulphonic Acids, and the Manufacture from these Acids of Yellow and other Dyes.* John Clayton Mewburn. A communication from Louis Freund, St. Louis, Alsace. Eng. Pat. 1069, Feb. 27, 1883.

THE naphthalene (about 44lb.) is heated with excess of strong sulphuric acid (100 kilos.) for 8 to 10 hours to a temperature of 160° to 200° C. In this reaction there are produced alpha- and beta- naphthalene-disulphonic acids which can be separated by means of the different solubility of their lime salts, but in practice the inventor appears to nitrate the mixture of acids by adding the theoretical quantity of nitric acid or a nitrate to the melt formed in the manner above described, after the completion of the sulphonation and the product has been allowed to cool. The nitration is complete in the course of some hours, when the product is diluted with water (44gals.) and the nitro-disulphonic acids reduced to the amido-disulphonic acids. The latter are converted into their lime salts and dried down. Dyes are produced by diazotising the amido-disulphonic acids, and combining their diazo derivatives with phenols, oxyphenols, their ethers or sulphonic acids, amines, etc. The inventor claims also the naphthol-disulphonic acids produced by boiling the foregoing diazo-sulphonic acids with water and the resulting diazo colours, obtained by combining them with diazo-benzene and its homologues, diazonaphthalene, diazo-azobenzene, etc.—R. M.

*New or Improved Processes for Producing Colouring Matters from Phenol.* Herbert John Haddan. A communication from the Leipziger Anilin-fabrik, Beyer and Kegel, Lindenau, Leipzig, Saxony. Eng. Pat. 3088, June 21, 1883. Provisional protection only.

THE colouring matter claimed is dinitrophenol para-sulphonic acid,  $C_6H_3(NO_2)_2.HO.HSO_3(NO_2)_2$ , obtained by the action of nitric acid upon potassium mononitrophenol-parasulphonate or by excess of dilute nitric acid upon phenylparasulphonic acid. Precautions have to be taken to prevent the formation of picric acid. The salts of this dinitrosulphonic acid are used as yellow dyes, and by the reduction of the nitro groups amido acids are obtained which can be made to furnish azo compounds in the usual way.—R. M.

*Improvements in Red Colouring Matters.* Frank Wirth. A communication from Kalle and Co., Biebrich, Germany. Eng. Pat. 3095, June 21, 1883. Provisional protection only.

THE colouring matters in question are produced by oxidising one molecule of a paradiamine with two molecules of a phenolic ether. Alkyl-derivatives of the diamine may also be used, and likewise such derivatives as contain oxidising atoms in their molecule, such as nitrosodimethylaniline or dichloroquinonimide. Where no oxidising atom is in the molecule, bichromate of potash is used. As examples the authors give (1) paraphenylene (or tolulylene), diamine and orthoanisidine hydrochloride; (2) paraphenylenediamine, orthoanisidine and aniline hydrochlorides; paradiamidodiphenylamine and orthoanisidine hydrochlorides; (4) Orthoanisidine hydrochloride and dichloroquinonimide; (5) nitrosodimethylaniline and orthoanisidine. The materials in examples (1), (2), and (3), are oxidised by bichromate of potash, or some other suitable oxidiser. The colouring matters (which belong to the safranin series) are red and fluorescent.—R. M.

## V.—TEXTILES, COTTON, WOOL, SILK, Etc.

*A New or Improved Process of, and Machinery for, Washing and Scouring Wool.* H. J. Haddan, London. Communicated by E. Tremsal, Loth, Belgium. Eng. Pat. 2983, June 15, 1883.

WOOL treated by this invention is placed "between two endless bands or sheets situated one over the other," and

is so carried a sufficient number of times through various washing and "grease-extracting baths." The object of this manner of working is to avoid "the felting, turning, and interlacing of the filaments" of wool which are apt to take place when it is agitated in a washing or scouring bath.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Application of Hydroxylamine for Printing.* Schaeffer. Bulletin de Mulhouse, 1883.

THE author has applied the energetic reducing properties of hydroxylamine,  $NH_2.OH$ , in order to discharge manganese brown. The hydrochloride,  $NH_2.OH.HCl$  must be used. On printing this upon a manganese ground the latter is instantly reduced to manganese chloride. A very dark indigo blue dyed on manganese is lowered to a lighter and brighter blue by the elimination of the  $MnO_2$ . In like manner nankin, chamois, and similar colours can be discharged white. It is thought that a cheap hydroxylamine would be useful for technical purposes, and the Société Industrielle de Mulhouse has offered a silver medal for a cheap method for the preparation of that compound.—J. G.

*The Fixing of Aniline Colouring Matters by Means of Metallic Sulphides.* Dingl. Polyt. Jour. 250, [4], 183-184.

BLANCHE first recognises the part played by a known sulphide as a mordant for aniline colouring matters. Sulphide of zinc or sulphide of tin precipitates the colours fuchsine, aniline-violet, Bismarck-brown, etc., upon cotton fibres. Lüssy has experimented in the same way with sulphide of antimony. He fixes the latter by impregnating the fabric with Schlippe's salt and decomposing with an acid. The precipitated antimony sulphide absorbs methylene-blue, malachite-green, rosaniline, and colouring matters of the same kind, in the colouring bath. Lüssy is in error when he says that the same action takes place in tanning with antimonious sulphide as with antimonious oxide. The latter serves for the perfect precipitation of tannin, which is the main mordant, and antimonious oxide alone cannot fix the colouring matter. In order to employ the mordant action of the metallic sulphide in steam-colouring, H. Schmid recommends the "hyposulphite" method. A metallic salt, of which the corresponding sulphide can be precipitated by the action of thiosulphate of sodium, is mixed with the latter salt and colouring matter. Upon steaming, the insoluble sulphide is precipitated along with the colouring matter. In this way in one operation it is possible to fix, by means of sulphide of cadmium, copper, lead, etc., methylene-blue, malachite-green, dimethylaniline-violet, etc. The colour obtained depends on the kind of sulphide and the colouring matter employed. Sulphide of cadmium gives a green colour with methylene-blue, but with aniline-green a yellowish green. These colours withstand the action of soap pretty well. A bright yellowish steam-green is, for example, obtained with 950 grammes of mucilage of tragacanth (containing 200 grammes to the litre), 200 grammes of crystallised cadmium nitrate, 300 grammes of crystallised sodium thiosulphate, 20 grammes malachite-green, 10 grammes of acetic acid of 7° B., and 150 grammes of water.—A. H. A.

*Perthiocyanogen as a Yellow Colouring Matter for Printing.* Heinrich Schmid. Dingl. Polyt. Journ. 251, 41, 1884.

THE fact that thiocyanic acid and its salts yield, under the influence of certain oxidising agents, yellow insoluble perthiocyanogen ( $C_3H_3N_3S_3$ ) has long been known, and Prochoroff has recently found that perthiocyanogen may be employed as a colouring matter, and has patented the industrial application of this compound under the title of "canarin." Potassium thiocyanate is oxidised by potassium chlorate in presence of hydrochloric and sulphuric

acids, and by this treatment yields about 40 per cent. of its weight of the colouring matter. Canarin appears as an orange-yellow heavy powder, insoluble in water, alcohol, and ether, but soluble in concentrated sulphuric acid and in caustic leys. Prochoroff claims its application to the printing of wool, but as regards cotton the fixation does not at first sight appear practicable, owing to the insolubility of perthiocyanogen in the ordinary reagents. The only method of applying it in cotton printing is to produce it in the fibre. This also is attended with difficulties, as it is not easy to prevent the fibre from being attacked during the very energetic action of the oxidising agents upon the thiocyanate. The author at first advised printing with a mixture of potassium thiocyanate, sodium chlorate, and metallic salts, which by double decomposition should give rise to easily decomposed salts of thiocyanic and chloric acids. Steaming would then affect the liberation of  $\text{HClO}_2$  and  $\text{HCNS}$ , and consequent formation of perthiocyanogen. It was found, however, that on steaming, an evolution of hydrochloric acid took place, sufficient to attack the fibre in the white spaces of the patterns, causing rottenness there, although the printed portions remained intact. It appeared not unlikely that by avoiding the necessity for steaming, this difficulty might be overcome, the reaction being promoted not by steaming but by the application of some vanadium solution, or by printing over such a mixture as is described above, with a paste containing vanadium. The simplest plan, however, is to print with the mixtures detailed here: 280 parts of thickening, 5 to 15 parts of vanadious chloride solution, 100 parts of commercial crystallised thiocyanate of aluminium, 100 parts of aluminium chlorate, 40 lb. The solution of aluminium chlorate is prepared by mixing 7,900 grms. of crystallised barium chlorate dissolved in 8 litres of hot water, with a solution of 7,900 grms. of crystallised aluminium sulphate in 5.5 litres of hot water. For the preparation of the vanadium solution 20 grms. of ammonium metavanadate are dissolved in 100 grms. of hydrochloric acid and 200 grms. of water, and reduced by means of 30 c.c. of commercial bisulphite of sodium. The mixture is warmed, and when solution is complete, and a blue colour has appeared, made up to 20 litres: 1 litre of this dilute solution, therefore, corresponds to 1 grm. of ammonium metavanadate, and is thus the same as that employed in the production of aniline black. The new yellow rapidly develops in the oxidation or drying chambers such as those designed for aniline black production, or the time requisite may be reduced from 24 or 12 hours by the employment of Mather and Platt's continuous aniline black aging machine. In both cases an even brilliant yellow is obtained, and the fabric is not weakened. A remarkable property of perthiocyanogen yellow is its stability. Neither concentrated alkalis or acids destroy it or dissolve it out of the fibre, and by nitric acid its tint is simply rendered lighter. Bleaching powder and boiling soap solution have no action upon it, and air and light alter it but slowly. Another characteristic of perthiocyanogen yellow is its property of acting as a mordant to the aniline colours such as methylene blue, aniline green, red, violet, and, in short, to that class whose members are constituted as amines. This reaction cannot be ascribed to the presence of sulphur in the fibre, as it still takes place after the sulphur has been extracted. Neither is it to be ascribed to a formation of hydrocellulose, since the fixation of the aniline colours takes place when the perthiocyanogen yellow has formed, whereas it was shown above that the rotting of the fabric, due to the formation of hydrocellulose, was invariably observed in the blank spaces of the pattern. As might be anticipated from its marked deoxidising powers, wool cannot be printed with the above mixture. In this case the yellow does not develop either by steaming or drying.—W. D. B.

*Thickenings, Resists, and Discharges, for Calico-Printing, as employed principally in England.* By Robert Bonreart. Monit. Scient. xiv., 507.

#### SECTION I.—THICKENINGS.

(1) Wheat starch. (2) Mixture of wheat starch and

British gum. (3) Light and dark British gum. (4) Gum tragacanth. (5) Mixtures of starch and gum tragacanth. (6) Foreign gums, such as gum senegal. (7) Mixtures of foreign gums and pipeclay. (8) Mixtures of British gum and pipeclay. (9) Flour. (10) Mixture of flour and potato starch.

1. *Wheat Starch*.—The manufacture of this product is ably treated on in Würtz's Dictionary, in an article by Professor Schützenberger. It may be classed with flour as the cheapest thickening agent. The advantages attending its use are the following: Low price, the whiteness of the paste, the small quantity of solid matter contained in a given volume of paste. When working wheat starch the following points should be borne in mind as conditions to be avoided: (1) When made too long beforehand starch paste becomes sour, loses plasticity, evolves water and ammonia, and becomes very thin. (2) Much acetic acid must be avoided in a colour containing starch, as even weak acids prevent the paste from forming properly, especially on heating. (3) Colours containing starch should not be used for printing large surfaces, as the paste is too elastic.

2. *Mixtures of Starch and British Gum*.—These are very much used, and by mixing the two substances in various proportions, suitable thickenings are obtained for the different colours. Light British gum should be used, as this contains starch but little altered and is cheaper than the dark variety. Formerly the boiling was done over the naked flame, this not rarely giving rise to considerable irregularity from overheating, especially when the paste is thick. At the present time the heating is done by means of steam, in pans furnished with a jacket, and when the paste has become homogeneous cold water is run in instead of steam. The mixing is mostly done by means of mechanical agitators furnished with a double motion of revolution and translation, the agitator being kept acting until the paste is quite cold; without this the paste will not be homogeneous. For the testing of starch and British gum a trial colour should be made in the laboratory, half a litre being quite sufficient, printed, and then compared with a feat done with a standard sample of the same thickening. To test for the presence of silicious sand, boil with excess of dilute  $\text{HCl}$ ; this dissolves the starch immediately and gives a clear solution. Filter and then weigh the sand which is always found in starch and the different kinds of flour. If there be too much sand damage is done to the rollers and the action of the doctor is interfered with. White starch occurs in commerce as large masses, at first sight resembling crystals, and this form is to a certain extent a guarantee of its purity, for the following reasons: (1) When potato starch is mixed with wheat starch the former prevents agglutination and causes falling to powder. (2) The small quantities of gluten retained by the starch cause its particles to adhere. (3) Impurities such as lime, inorganic salts, etc., intended to whiten mouldy starch which has become gray, or added for weighting purposes, interfere with the interadherence of the starchy particles. British gum is sold as an impalpable powder of a more or less brown colour. Sometimes manufacturers mix over-burnt starch with that which has not been heated at all. This fraud is detected at once on printing, or else on inspection with the microscope. Concentrated alkalis thicken very much starch and British gum pastes by enormously swelling the granules. This takes place in the cold, and the same phenomenon is observed with mixtures of starch and water which have not yet been boiled. Use is sometimes made of this property for resists, for alkaline red mordant (aluminate of soda), and for thickening colours like natural indigo (steam).

3. *British Gum*.—This is a calcined starch occurring in light and dark varieties, and obtained by subjecting starch to various temperatures. It is distinguished from dextrine by being but little soluble, and giving a paste when heated with water. Its advantages and disadvantages, of a different nature to those of starch, are the following: Less susceptibility to the action of acids, it being quite allowable to heat this substance with a large excess of acetic acid for a long time; the paste is very smooth, and keeps a long time without breaking or

becoming thin; it forms an excellent thickening for grounds and blotches, being less elastic than starch, and thus filling up the parallel lines in the engraving. As disadvantages may be mentioned—price, brown colour, and larger quantity of British gum required than of starch for the same thickness of paste.

4. *Gum Tragacanth*.—This is the dried juice of an exotic shrub of the species *Astragalus* and possesses a very great thickening power, 20 grms. per litre being sufficient to give body to a printing colour, whereas 125 of starch or 200 grms. of British gum are required for the same effect. Gum tragacanth occurs in flattened drops, hard and of fibrous structure, sometimes bleached by chlorine to improve the colour. Alone this gum is almost solely used for thickening albumen colours as these should be washed but little, and hence require a thickener containing but little solid matter and giving a perfectly transparent paste. Much of this gum is used in mixture with starch. Since gum tragacanth is difficult to dissolve even on continued heating, it is usual to prepare a stock of standard paste containing 60-70 grms. per litre, and this is then used as required. When once properly prepared it keeps a long time without alteration. Mixtures of tragacanth and starch are exceedingly useful, being thicker than those made with starch alone, and yet more unctuous. They keep a long time and are gaining ground, especially for light designs and finely-engraved patterns.

6. *Foreign Gums*.—These are so termed to distinguish them from British gum, and consist of products obtained from the various trees of the species *Acacia*. Their properties differ but little, and they are mostly classed by quality. These gums occur in commerce as yellow or reddish-rounded fragments, opalescent and with a resinous fracture. The less dust and vegetable debris is present the better. Solution takes place easily in hot water, and extensive use is made of these substances in printing. The better qualities are used for thickening light and delicate shades, such as light alizarine, pinks, or light shades of aniline colours. Grounds on which patterns of a deeper shade are to appear are got in this way, as these gums insure great regularity of shade, owing to the presence of much acetic acid being allowable, and this prevents the weakening of the colours before printing, by retarding combination with the mordant, combination taking place only on steaming. Large quantities of these gums are required, 300 grms. per litre giving only a thin paste. A great advantage lies in the transparency and also the brilliant appearance of the printed portions. Medium and low qualities are mixed with pipeclay and used as resists, as, e.g., with dyed indigo. The salts intended to produce the white are incorporated, and the mechanical action of the gums and clay is then of considerable assistance.

7. For resists to be used with a chemie bath the above-mentioned mixed thickening is again used in conjunction with oxalic acid, and it is found that gums stand the action of strong acids much better than other thickening agents. These so-called foreign gums seem to contain metals of the alkaline earths in combination with weak acids. When thickening alizarin pinks with gum senegal, the addition of acetate of lime may be dispensed with, this being absolutely indispensable when mixing for pink with starch. Mixtures of foreign gums and starch are not workable, as pastes made thus soon become fluid again.

8. *Pipeclay*.—This is never used alone. Its use in conjunction with gum has already been mentioned, and often a mixture has been made with burnt starch, for citric resists with alumina or iron acetate mordants.

9. *Flour*.—This is used for thickening alumina or iron mordants, as the gluten contained cannot injure the colours, since all it does is to fix the metallic oxides in the cloth, and everything else is removed in the dunging, etc., operations. Potato starch, being cheaper than wheat starch, is sometimes mixed with flour. Rice starch and maize starch (corn starch) are not much used for thickening, but all the more for finishing with kaolin, a little gelatine being added for stability.

#### SECTION II.—RESISTS.

These invariably consist of pastes, made up with

various drugs and thickenings, which are printed on the cloth to prevent other colours being fixed at certain places. They may be divided into resists for white and coloured resists—e.g., those containing a different colour to the one it is desired to prevent being fixed. For each class of printing colours there is a different resist, made with the object of annihilating the power that this kind of colour has of fixing itself on the fibre. We have mechanical and chemical resists, the first class being represented by pipeclay. The second class is very large, and much in use.

*Resists with Alumina or Iron Mordants*.—These are very important resists, especially in conjunction with acid acetate of alumina, which is also termed red liquor, and is one of the most useful mordants in dyeing, as it serves to fix not only alizarin for turkey-red, ordinary alizarin red, dyed pinks, and such colours, but also when used with tannin serves for all anilines, such as methylene-blue, malachite-green, etc., and finally for wood colours. Iron pyrolignite is a similar mordant, being used either alone or else mixed with red liquor for all shades in which alizarin is the colouring matter—the scale of tints running through black, violet, chocolate, brown in various shades, and finally the red of the pure alumina lake. In order to understand how to prevent these mordants being fixed it is first necessary to discuss the manner of their fixation. The alumina and iron mordants, when printed on the cloths, are dried on tins, or else in hot rooms, and then passed into the warm moist atmosphere of the Crum oxidising chamber. The heaps of cloth are then exposed to the ordinary temperature for 24 to 48 hours. In this way the acetates are decomposed into insoluble oxides, and acetic acid, which evaporates as fast as it is liberated or is removed in passing through the subsequent becks. It is now easy to understand how the alumina or oxide of iron may be prevented from being fixed by means of a resist. It suffices to print a sufficient quantity of a non-volatile acid, such as citric, tartaric, or oxalic, to avoid the fixation of the oxides. These are, indeed, temporarily formed, but combine again to soluble salts (citrate, tartarate, etc.), which are removed by washing. Often lime juice is used as a resist, as it is cheaper than crystallised citric acid, and works quite as well. Citric acid is better than tartaric acid. The former does not form an insoluble compound with the lime frequently contained in thickeners. Tartarate of lime clogs the engraving on the roller, and prevents good printing. Resists like the above, being very acid, must be thickened with British gum, for starch cannot stand strong acid at all.

*Alumina Resist with Iron Mordant*.—This is based on the property possessed by stannous chloride of preventing the iron of ferrous pyrolignite from becoming insoluble without opposing any obstacle to the fixation of the alumina of red liquor. Print a mixture of red liquor and stannous chloride, dry, then print on the pyrolignite of iron, which will only be fixed where the resist has not been printed. In this manner we may obtain plain violet grounds, or grounds made up of lines parallel or otherwise, with floral or other patterns, not covered with violet.

*Resist in Orange or Yellow with Iron Mordant*.—Iron mordant is sometimes resisted by means of a mixture of sugar of lead and citric acid. Here the iron is not fixed owing to the citric acid, and the lead is rendered insoluble either by preparing the cloth with sulphate of soda before printing or else by means of baths of sodium sulphate and phosphate before dunging. The yellow is formed after dyeing up in alizarin by a bath of bichromate of potash, yellow lead chromate being produced, which may be turned orange by lime water.

*Resists with Dyed Alizarin and Anilines Fixed in the Resisted Parts*.—Steam aniline colours are got up as follows: Print a thickened paste of the colour, tannin and acetic acid, and dry and steam for an hour. As a rule, the printing is done on cloth prepared with stannate of soda and dilute sulphuric acid. When the colour is dried on the cloth and then steamed, the acetic acid is volatilised and an insoluble double tannate of tin and colour is formed. For the case in hand, we cannot employ a tin prepare for the cloth, since when dyeing up the reds the

whites would come up pink, and the blues and greens would have no brilliancy. To avoid this taking place, pass the cloth through a tartar-emetie bath after steaming. The antimony combines with the tannin in the colour, and thus fixes the blue or green sufficiently well to stand dunging, red dyeing, brightening, soaping, etc., etc. Aniline colours intended to resist the alizarin or iron mordant, must contain a fixed organic acid, such as oxalic or tartaric, besides the above-named ingredients. Citric acid should not be used, as citrate of alumina decomposes on steaming, and yields insoluble alumina. The same resist may be worked with steam colours. As an example we may take steam alizarin red, e.g., a printing colour containing alizarin mixed but not combined with mordants. After printing, the alumina lake is formed on steaming. Give a slight soaping to remove thickening and impurities, wash in running water and dry. The resist anilines will completely prevent the lake from forming, and yet will give insoluble tannates. Their colour comes out perfectly when all alizarin has been removed by soaping.

**Resists with Aniline Black.**—These are almost as important as those with mordants, and indeed large quantities of goods are turned out with aniline black grounds and resists in white, red, pink or other colours, being fixed by dyeing on a special alumina mordant. Aniline black being a very acid colour, it only develops on the cloth when still very acid, and hence the best means of resisting it is to print on a neutralising agent or a reducing agent, as e.g., stannous chloride.

**White Resist.**—This is worked with a paste of burnt starch and caustic soda, or else the carbonate. Sometimes citric acid, or rather lime juice, is also added.

**Red and Pink Resist.**—Use is here made of the so-called alkaline red mordant, viz., a solution of hydrate of alumina in caustic soda. When aluminate of soda is dried by prolonged exposure to air it is decomposed into caustic soda and alumina hydrate, which take up CO<sub>2</sub> from the atmosphere and are converted into carbonates. Print the alkaline mordant, dry, pad with aniline black not yet developed. The hydrochloric acid of the black combines with the soda of the aluminate of the mordant, the alumina is precipitated and fixed, but the black will not form, as the mixture is not acid enough. Give a few minutes in Mather and Platt's aging machine, hang for two days, wash and dung as usual, and then dye up in alizarin or else pass through tannin for anilines. If several strengths of mordant are to be printed do not let down simply with neutral starch paste, but add the white alkaline resist mentioned above, otherwise the black will not yield.

**Resists with Dyed Indigo.**—For white print a solution of copper sulphate thickened with gum and pipeclay. The copper sulphate oxidises immediately all dissolved and reduced indigo, which comes in contact with the fibre, and thus avoids entrance and fixation, the pipeclay only acting mechanically. For yellow, mix sugar of lead with the bluestone. When dyeing in the strongly alkaline vat the lead is precipitated on the fibre, a bath of dilute hydrochloric acid gives the slightly-soluble lead chloride, and a passage through bichromate of potash yields the required yellow chromate of lead, which can be changed to orange by lime water. Stannous oxide resist is much used with steam methylene-blue. The oxide of tin is prepared by precipitating stannous chloride with carbonate of soda, washing the precipitate on a woollen filter, and thickening with starch or otherwise.

### SECTION III.—DISCHARGES.

This is another means of altering styles for printed goods, and is of great importance. We have both white and coloured resists, the former being produced by action on the colour and the latter by acting on the mordant alone. Both have as their object the destruction of the colouring matter or the mordant already fixed on the fibre, and this without injury to the strength of the fabric.

**Discharges on Turkey-Red.**—Turkey-red is an alizarin red of a shade identical with that of alizarin reds dyed by the ordinary process. It differs, however, from the latter by an extraordinary fastness, which allows it to stand the action of boiling alkaline leys. It is the

alizarin-alumina lake, more or less combined or mixed with oils altered and rendered drying, which protects the colouring matter from the action of chemicals. In this case, discharges are worked by means of a bath of bleaching liquor. As long as this is neutral, or slightly alkaline, the red keeps very well, but is immediately destroyed when the beck becomes acid; for while it is merely necessary to print tartaric acid, thickened with pipeclay and gum, before passing into concentrated bleaching liquor, made alkaline with lime-water, a thorough washing in running water is essential to free the cloth from the liquid, which otherwise would soon decolourise it in contact with the air. For yellow add a lead salt to the discharge mixture for white, and then pass through potassium bichromate solution. For blue it is usual to employ Prussian blue, this being the only blue which will stand chlorine and acids. A green discharge is got by means of a mixture of Prussian blue and a lead salt. For black it is not necessary to previously destroy the red. As a rule the blacks are obtained by superposing Prussian blue and ferrous sulphate on the red. The sulphate of iron yields the hyalate, and the combination of blue, red, and brown, produces a black. Logwood extract is also added, and this is fixed in the chlore bath, either by combination of the iron precipitated from the ferrous sulphate or else by being rendered insoluble by the lime in the liquor.

**Press Discharge on Turkey-red (Bandanna style).**—Although almost of purely historical interest, this style is perhaps worth mentioning. The dyed cloth, in layers of 12 or 14 pieces, was clamped in a hydraulic press, in which top and bottom plates were perforated to pattern. A mixture of muriatic acid and bleaching liquor, practically forming chlorine water, was forced through the perforations by means of a pump. After slackening the pressure, that part of the pieces just discharged falls into a trough of water; following portions are consecutively discharged in the same manner, following the first portion into the water-trough, and so on until the entire lengths of the pieces are finished. At present with improved machinery the work is done more quickly by printing on the acids, and then passing through the bleaching liquor.

**Discharges on Vat Blue.**—This process is based on the action of energetic oxidising agents on indigo in an acid medium. Theoretically we have here something similar to a discharge on Turkey red, but in practice the analogy does not hold. Neutral chromate of potassium is printed on the indigo dyed cloth, the fabric is dried, and then passed through a mixture of dilute sulphuric and oxalic acid, not strong enough to injure either the blue or the fibre, but strong enough to liberate chromic acid. Destruction of the blue ensues, the pattern is obtained, and thorough washing completes the operation. Coloured discharges are worked with albumen as follows: Add to the chromate of potash mixture some albumen and pigments capable of resisting strong acids, and in an impalpable powder. The acid bath in this case both liberates chromic acid and also coagulates the albumen, thus rendering it insoluble in water, acids, and soap solutions. Indifferent mineral pigments being numerous, attractive effects can easily be obtained. Thus for reds, cinnabar, red chromate of lead; for yellows and oranges, the various lead chromates; for greens, Guignet's green (hydrated oxide of chromium).

**Ferriyanide Discharges on Vat Blue.**—This is a novel process, which allows the fixation of alumina mordant by printing on dyed indigo, destroying at the same time the colouring matter on the printed places. To obtain simply a white discharge on indigo, proceed as follows: Print a thickened mixture of ferriyanide and caustic soda, steam, and wash. When the intention is to fix an alumina mordant, the caustic soda should be replaced by aluminate of soda. On washing, insoluble alumina is obtained in the cloth, and it can then be dyed up with alizarin as usual.

**Discharges on Manganese Brown.**—It is usual to discharge the same series of designs on manganese brown as on vat blue, but the fastness of the colours is not as great as in the former case, for the aniline and phenol colours employed in this case fade when exposed to light; the

brown cannot stand even weak acids, and hence these prints are decolourised by perspiration. Stannous chloride, owing to its reducing action, is much used here as a discharge. Thus, by printing a thickened colour containing tin salt and eosine, the colouring matter goes on as a colourless phthaline in combination with the tin, but, on steaming, the colour reappears, and is well enough fixed to stand a light soaping, which is, however, mostly omitted. The colours mostly employed for this style of work are catechu browns, eosines, lake of tin and Persian berries, special aniline blue resisting tin salt. The carminaphite made by MM. Durand and Huguenin, Basle, has also been tried, but is found to mark off by slow sublimation when the goods are kept in stock.—H. A. R.

*Improvements in Fixing Colours on Fabrics and in Apparatus connected therewith.* Arthur William Kirk, (J. M. Kirk and Sons, Halifax.) Eng. Pat. 3422, July 11, 1883.

IN the ordinary process of dyeing the dyed goods after being thoroughly washed are placed on a table and passed over a series of hollow rollers heated internally by steam. "With fabrics thus dyed, and more especially lustre goods employed by tailors for linings, when the tailor's iron is applied to the seams to iron the same, the colour fades or flies as the damp cloth employed by the tailors draws out the colour or colours." In order to obviate this difficulty the inventor has devised an apparatus consisting of a drying chamber fitted internally with a series of wooden rollers and ventilated by a blast of cold air. The fabric passes backwards and forwards over the rollers or remains stationary till dry, after which it is straightened over a heated cylinder and pressed or "tentured" if necessary.—R. M.

*Improvements in the Mode of Subjecting Textile Materials in Filamentous or Band Form to the Action of Dyeing, Bleaching, and other Liquors, and in Apparatus for that purpose.* Friedrich Carl Glaser, Berlin. A communication from Eugen Rummelin, Alsace. Eng. Pat. 5090, Oct. 26, 1883.

THE object of this invention is to avoid the felting or matting together of the fibres of textile fabrics which results from the operations of cleansing, bleaching, mordanting, dyeing, and rinsing as at present carried out. The apparatus described and figured in the patent consists essentially of a compound skeleton revolving reel, round which the filamentous or riband-like material can be stretched and immersed bodily in the vat containing the dyeing, bleaching, or cleansing solutions. Several of these reels can be kept going in the same bath if necessary. The advantages claimed for this method of manipulating the fabric in the bath in a stretched condition are the avoidance of felting, the treatment of considerable lengths of material without handling, the possibility of working in closed vats so as to secure uniformity of shade, and finally, the applicability of the process to existing works at a comparatively small cost.

R. M.

*Improvements in the Construction of Apparatus Employed for Bleaching, Washing, Chloring, Scouring, Soaping, Dyeing, and Dyeing Woven Fabrics.* J. Farmer, Salford. Partly communicated by A. Lalancée, Mulhouse. Eng. Pat. 2871, June 8, 1883.

THIS invention "is intended to do the work much quicker, and in a more effective way, by forcing the liquor to penetrate the fibres of the cloth by a mechanical process." "The cloth is supported by hollow metallic cylinders or rollers, perforated with holes over their surface the whole width of the cloth, and corrugated lengthwise to allow the liquor to pass freely through the cloth and out or into the holes on the surface. Inside the hollow rollers or cylinders a certain vacuum or pressure is produced to force the liquor to penetrate the cloth, either by forcing the liquor inside the cylinder or roller and through its perforations through the cloth, or

by producing a vacuum inside the cylinder or roller, and thus drawing the liquor through the cloth and into the cylinder or roller." A detailed drawing of the apparatus is given.

*An Improved Method or Process of and Apparatus for Dyeing Textile Fabrics.* Henry Harris Lake. A communication from La Société Anonyme des Teintures et Apprêts de Taras-e, France. Eng. Pat. 2906, June 11, 1883.

BY means of this apparatus the fabric, previously prepared by mordanting, etc., is kept continuously moving over rollers in the bath, whilst the solution of the dye is allowed to flow in from a separate cistern provided with a regulator. In this way uniformity of shade is obtained, and the amount of colour can be continuously regulated so as to meet the requirements of any particular fabric.

R. M.

*Improvements in Dyeing Silk or other Textile Fibres.* Thomas Holliday, Huddersfield. A communication from Eugene Rau, South Manchester, Connecticut, U.S.A. Eng. Pat. 2668, May 29, 1883.

THE colouring matter is chosen so as to be soluble in oil or fatty acid, or a mixture of the two solvents, the dye-bath, if requisite, being diluted with carbon disulphide, benzene hydrocarbons, or petroleum. When dyed the fabric is pressed, steamed, and the oil removed by a suitable solvent. This process is said to be especially applicable to "plushes, velvets, faille silks, ribbons, laces, and fabrics in which the lustre of the silk requires to be preserved."—R. M.

## VII.—ACIDS, ALKALIS, AND SALTS.

*Improvements in the Salt Industry.* Dingler's Polyt. Journ. 250 [8], 365-369. *Improvements in the Boiling-down Plant of the Salt Works at Ischl.* C. v. Balzberg, Oesterr. Zeitschr. für Berg- und Hüttenwesen, 1883.

THE author calculates that if the brine indicates with the hydrometer a specific gravity showing that it is only 0.1 per cent. weaker, a loss in fuel amounting to 0.5 per cent. is incurred in evaporating to obtain the salt. The hydrometers which have been used up to the

present are not sufficiently accurate to indicate such small differences. Fig. 8 represents a new hydrometer, the scale of which shows divisions for 0.05 kilo, per hectolitre. The readings are made by means of a float, which renders it possible to estimate even 0.1 kilo. The standard temperature for which this hydrometer is graduated is 18.75° C.; and a table has been calculated by Balzberg to make corrections for any other temperature. The waste steam was used for heating up the brine in open pans; but this arrangement takes up much room,

gives a rough discoloured salt, and requires special attention, so that it has in many places been given up. The arrangement used in Ischl consists of three vessels C (Fig. 11). They are made of sheet iron, 4mm. strong, riveted together, and are connected with one another by tubes at the top and bottom. Each of these vessels is 4m. long, 1.5m. high, and has a clear depth of 0.16m.; so that the acting surface is 40 square metres. The apparatus can be easily cleaned by opening the six flanges *m* at the bottom and flushing with water. It has been found necessary, in order to work this apparatus to advantage, to give up the usual system of feeding the pans discontinuously,

which is equal to a saving of 656 kilos. of coal from Traunkthal of 3,000 calories effect. In Alpine saltworks Schwind's measuring trough is used, as well as the system of measuring in large vessels of known capacity—the so-called chamber measuring. The measuring trough has been found inaccurate, and the chamber measuring takes up too much room. The apparatus represented in Fig. 12 has been found satisfactory. The centre of gravity is made movable by means of the weight *a*. In order to equalise this weight it was necessary to make the angle which the brine forms with the bottom of the vessel more pointed. In order to graduate this apparatus it is

Ischler Furnace Plant  
for the Manufacture of Salt

The depth of the brine in the pan is regulated by a copper float *s*, which by means of a valve *v* regulates the supply from the heater in such manner that the level is kept constant. A float *c* in the trough *d* regulates the supply of brine at *f*, from which place the brine has first to pass the tipping trough *g*. A registering apparatus *z* (Fig. 13, and connected with Fig. 11) thus indicates the quantity of brine consumed in the pan. If the average temperature of the steam on leaving is 43°, the brine is raised in the heater from 0° to 40°. On a daily consumption of 67,673 kilos. brine, the specific heat of which is 0.8384, this corresponds to 2,269,500 calories taken up daily by the brine,

only necessary to run a known quantity of brine through it, and to move the weight *a* up or down, according to whether the results indicated are too low or too high. The final graduating is done by fixing or taking off small metal plates on or from the weight *a*. Each of the two vessels holds 5 litres. The indicator shows every second tipping, and it is therefore only necessary to divide the number shown by the indicator by 10 in order to obtain the number of hectolitres which have passed. The scarcity of wood in the Salzkammergut induced the management to try other fuel as well. Producers were also tried, which were first built on the

system "Heupel," but were gradually altered into the form shown in Figs. 9 and 10. As the gases were used for directly drying the salt, perfectly clean combustion was absolutely necessary. Fig. 9 shows the construction used for coal, and Fig. 10 that used for wood. The hot air meets at a right angle by passing through the slits *b* with the gases which pass through the slits *a*, and gets mixed with the latter before entering the combustion chamber *c*. The following results were obtained on analysing the gases from the original design (I.) from the furnace (Fig. 10) (II.) and from the cross-producer (Fig. 9) (III.):—

	I.	II.	III.
Carbonic acid.....	11.2 ..	14.0 ..	15 ..
Carbonic oxide .....	2 ..	0 ..	0 ..
Oxygen .....	9.0 ..	5.5 ..	4 ..
Nitrogen .....	79.6 ..	80.5 ..	81 ..

The cross-producers worked best, and yielded perfectly white salt. On burning Traunthal coal in the producer (Fig. 10), there was obtained on an average 137.3 kilos. salt for every 100 kilos. of coal; whereas the ordinary way of firing yielded only 117 kilos. salt, a saving in favour of the producer of 13 per cent. in fuel. The same producer was used for wood, but instead of the grate a plane inclined to the front was applied, and slits for the air supply. In the producers (Figs. 9, 13, and 14) the air enters at *f*; the current then divides into the channels *g* and *h*; *g* goes backward and passes through the channel *i* into the chamber *k*, where it is strongly heated and passes back into the producer. The air in the channel *h* passes through *l* and *n* into the opposite side of the burner. The feeding layer was raised to 1.15 metres. It was found that the producer gave a saving of 14.8 per cent. in wood as compared with the results obtained by the old way of firing.—J. G.

*On certain Basic Sulphates.* J. Habermann. Monatsch. f. Chem. 4, 787.

THE author has prepared a number of basic sulphates of nickel, cobalt, zinc, and cadmium by imperfectly precipitating the solutions of the normal sulphates with ammonia and with sodium carbonate. In their mode of formation these compounds resemble the sulphate  $6\text{CuO} \cdot 2\text{SO}_3 \cdot 5\text{H}_2\text{O}$ , described by Gmelin (vol. 3, 6 ed., p. 628) and by Pickering (*Ber.* 16, 1360). In composition, however, the analogy is not maintained. This paper is a preliminary notice of a full investigation of the subject.—C. F. C.

*Improvements in or Appertaining to the Concentration or Purification of Commercial Sulphuric Acid.* W. Jones Menzies, St. Helens. Eng. Pat. 3230, June 29, 1883.

THE author of this invention has "discovered that a pure hydrated sulphuric acid—that is to say, some 3 or 4 per cent. stronger than the ordinary 66 Baumé acid of commerce—can be obtained by distilling the ordinary pyrites vitriol as obtained from the Glover towers in an iron vessel or still connected with a suitable condensing apparatus, preferably a range of thin glass pipes, in which the fumes of hydrated sulphuric acid passing over from the still are condensed, and a pure hydrated sulphuric acid thus obtained. It is necessary that the acid should be of a concentration not less than that usually coming from Glover towers—that is to say, not less than 58 Baumé—and also that the arsenic shall exist in the form of arsenic acid, which is generally the case with commercial vitriol after passing through Glover towers, owing to the action of the nitric acid in the nitrous vitriol when passing through the Glover tower in the usual manner. If the vitriol to be purified and concentrated by distillation has not been passed through a Glover tower, but is simply chamber acid, it must previously be concentrated in leaden pans, with afterwards a small addition of nitric acid, or some other oxidising agent, so as to convert all the arsenic existing in the form of arsenious acid into arsenic acid. If acid of a less strength than 58 Baumé is used, there is some action on the top of the iron still, and unless the arsenic is completely oxidised into arsenic acid, it will pass over with the fumes of hydrated sulphuric acid, instead of being left

behind as an insoluble deposit at the bottom of the still. If vitriol, however, of a degree of concentration of not less than 58 Baumé be used, there is no action at all on the iron still below the surface of the boiling acid, and only a very slight action on the top of the still, when the first portions of water contained in the commercial vitriol pass off, together with some sulphuric acid, the action ceasing entirely as soon as the last traces of water have passed away." The apparatus and one mode of working are described as follows: "An iron kettle with straight sides, the metal varying in thickness from two inches at the top, where there is the greatest wear and tear, down to one inch at the bottom, has a movable iron top two inches thick, fastened on to the kettle with a tight joint. An iron elbow pipe is either fastened to the top, or forms part of it, and is arranged at such an angle that any condensation taking place in it can run back into the iron still. A small inner flange is placed at the end of the pipe to completely arrest any condensation of acid in the iron elbow-pipe being carried forward. The cooling and condensing range is constructed preferably of thin taper glass pipes, such as are now extensively used for condensing muriatic acid, fitted into each other and set at a slight inclination, so that the fumes of hydrated sulphuric acid, as condensed, shall flow down them and through the draw-off pipe to the cisterns. A leaden tower filled with flints, glazed bricks, or some other equivalent substance not acted upon by sulphuric acid, condenses the last traces of escaping sulphuric acid, and through this a small stream of water may be passed, the better to effect this object by cooling and condensing these sulphuric acid fumes. The still is provided with a feed-pipe and man-hole for cleaning out or removing from time to time the deposit of arsenic, iron, and other impurities which collect at the bottom of the iron still. A heating flue from the fire-place is so arranged that neither the bottom nor top of the still are exposed to the direct heat of the fire. In working the apparatus described above, the still is first filled nearly to the top with vitriol, preferably coming hot from the Glover tower, and the fire is brought to bear upon it. At first sulphuric acid with steam passes off, forming weak acid, which can for the most part be drawn off into the cistern, or the whole of it allowed to run into the bottom of the condensing tower. As soon as the last traces of steam have passed away, pure hydrated sulphuric acid begins to distil over, and is almost immediately condensed in the row of glass pipes. This acid is drawn off into the lead cistern, which can be cooled if necessary by a coil of lead pipe with water running through it. This operation proceeds until the acid is distilled away down to the point immediately above the fire flue. The still is then refilled with acid by the feed pipe, and the operation commenced again and carried on continuously until a large accumulation of arsenic, iron, and other impurities collects at the bottom of the still, which can then be removed through the man-hole, either completely or the chief part of them, by fishing them up with an iron scoop." Another mode of working is afterwards recommended: "By thoroughly oxidising the arsenious acid and ferrous sulphate in the sulphuric acid, and heating the latter to distillation point, the arsenic and iron become insoluble in the concentrated hot acid and are precipitated in the pan or still, while acid is distilled off. The acid remaining in the still, after distillation has proceeded a short time, if withdrawn from the still without withdrawing the sediment, will be found practically free from iron and arsenic; and it will, probably, be found eventually the best plan to proceed on these lines—namely, fully oxidise the arsenic and the iron salts in the acid by means of nitric acid, boil or distill off a portion of the liquor in an iron still or boiler till the maximum strength of acid is attained, then let the precipitate settle, and decant off the hot acid."

*An Improved Manufacture of Gaseous Hydrochloric Acid.* C. D. Abel, London. Communicated by R. Hasenclever, Aix-la-Chapelle, Germany. Eng. Pat. 3393, July 9, 1883.

"HYDROCHLORIC acid in gaseous form, such as is specially suitable, on account of its purity, for the manu-

facture of chlorine according to Deacon's process, is obtained from aqueous hydrochloric acid by mixing therewith sulphuric acid, preferably hot, in chambers or towers of stone, earthenware, or suitable metal, the liberation of the hydrochloric acid gas being accelerated by blowing in air or stirring. The diluted sulphuric acid obtained by this process can be concentrated by evaporation and used over again."

*Improvements in the Manufacture of Chlorine.* H. A. Dufrené, Paris. Communicated by E. Geisenberger and "La Société Anonyme de Produits Chimiques, Etablissements Malétra," Paris. Eng. Pat. 3104, June 22, 1883. Not proceeded with.

HYDROCHLORIC acid is to be placed "in contact with zinc in a vessel or receiver containing plates of zinc and plates of carbon arranged alternately, so as to serve as a battery." The current generated by this battery, aided by a further current from some other sources is to be employed to decompose into its elements zinc chloride placed in "a second vessel or receiver, also containing plates of carbon and zinc arranged alternately." In the second vessel, zinc is to be deposited on the zinc plates, and chlorine liberated at the other electrodes. The zinc chloride to be electrolysed in the second vessel is to be that formed by the reaction upon each other of the hydrochloric acid and zinc of the battery.

*Improvements in the Treatment of Natural Basic Phosphates of Lime in the Leblanc Process for the Manufacture of Soda and Potash.* J. H. Johnson, London. Communicated by Crespel Brothers and Martin, Lille (Nord), France. Eng. Pat. 2990, June 15, 1883.

THE authors of this invention propose to use, in the black-ash operation of the Leblanc soda process, instead of calcium carbonate, native calcium phosphates; thus obtaining "balls" consisting essentially of calcium sulphide and sodium phosphate.

*Improvements in the Manufacture of Compounds of Alumina.* T. L. Gregson Bell, Stratford, Essex. Eng. Pat. 3388, July 9, 1883. Not proceeded with.

KAINIT or carnallite is added to a hot solution of sulphate of alumina, the product allowed to settle, and then the clear liquor decanted off. As the latter cools, potash alum crystallises out.

*Improvements in the Manufacture of Arseniate of Soda.* F. C. Blythe, Accrington, Lancashire. Eng. Pat. 3291, July 3, 1883.

THE author of this invention proposes to obtain arseniate of soda by heating together, "in a furnace, or in a crucible, retort, or any vessel of suitable form and material," a mixture of "arsenic acid, in the solid or liquid state, with common salt, in the proportion of 1 part of salt to 2 parts of anhydrous arsenic acid, or its equivalent containing water." The chlorine of the salt is given off as HCl, which may be condensed in the usual way.

*Improvements in the Manufacture of Chromates of Soda, and in relation thereto.* E. P. Potter and W. H. Higgin, Bolton, Lancashire. Eng. Pat. 3229, June 29, 1883.

CHROME ore is to be furnace "with lime or carbonate of lime and a suitable proportion of a sodium salt, but preferably the sulphate." The product is to be lixiviated with water, and the resulting solution to be exactly neutralised by hydrochloric acid. The neutralised solution is next to be evaporated, sodium chloride and sodium sulphate being fished out as they fall. When these have been removed, the mother-liquor is to be boiled down to dryness, and the solid residuum then to be "perfectly dried, but not fused, in a top-fired mechanical pan, or by other means, care being taken to keep the temperature low," and also to keep free oxygen in contact with the salt. The product is a mixture of bichromate and chromate of soda.

*An Improved Method of or Process for Extracting Ferrocyanides from Substances containing the same.* Dr. Hugo Kunheim, Berlin, and H. Zimmermann, Wesseling, Germany. Eng. Pat. 3342, July 5, 1883.

THE inventors take "the refuse or waste products from the manufacture of gas," and desulphurise them "in the ordinary manner." The solid residue "is subsequently mixed with dry pulverised caustic lime." The mixture is then heated "to from 40° to 100° Celsius, in order to partly expel the ammonia from its insoluble combinations, the ammonia which thus escapes being condensed in the ordinary manner." By then lixiviating the mass there is obtained a solution of calcium ferrocyanide. This is then "evaporated by steam, and mixed with as much chloride of potassium as is required for the formation of ferrocyanide of calcium and potassium,  $\text{CaK}_2\text{Fe Cy}_6$ ." By then boiling this double ferrocyanide with potassium carbonate, "yellow prussiate of potash" is obtained. An alternative method of working is described.

*Improvements in Apparatus for Burning Small Pyrites, and Calcining Ores and other Minerals.* M. Finch, W. Willoughby, J. Willoughby, and S. Willoughby, Plymouth. Eng. Pat. 2913, June 12, 1883.

THIS apparatus is a kind of "shelf burner," the ore to be calcined in it being fed by means of a hopper to the upper shelf, and being afterwards caused to pass over all the other shelves, the solid residue of the operation being discharged at the bottom of the apparatus. The shelves, instead of being placed horizontally, like those of the Perret, Malétra, and Schaffner pyrites burners, are inclined, alternately in opposite directions.

*Improvements in Hampers or Baskets for Transporting Bottles or Carboys of Acids or Other Corrosive or Dangerous Materials, Colours, Varnishes, or the like.* H. Brunner, Wilnes. Communicated by C. Garneri, Paris. Eng. Pat. 3190, June 27, 1883.

"THIS basket is built up of numerous standards of wood, thin and elastic. The base is preferably composed of two conical and concentric rings, thin, and of five to six centimetres in diameter. The standards are bound and fixed at equal distances between the two conical rings. Wooden rings placed at intervals in the height of the basket are fixed as well on the exterior as interior by means of a jointed mould, which gives to the basket the desired contour, according to the carboy or other article it is intended to contain."

*Improvements in the Manufacture of Ammoniacal Products, and in Apparatus therefor.* L. Q. Brin and A. Brin, Paris. Eng. Pat. 3089, June 21, 1883.

IN the specification of the patent 1416, of the 7th April, 1880, the authors of this invention described a method of obtaining barium dioxide by causing barium oxide to absorb oxygen from atmospheric air. Their present invention consists in passing over "barytic coke," heated to 1470° F., the mixture of oxygen and nitrogen, comparatively rich in the latter gas, which remains when some of the oxygen of atmospheric air has so been absorbed by barium oxide, thus forming barium cyanide, and in then obtaining ammonia by passing steam over that product at about 570° F.

*Process for the Preparation of Anhydrous Sulphuric Acid, and Description of Apparatus.* W. Rath, Plattenberg, Westphalia. Ger. Pat. 22118, Aug., 1882.

THE gases which leave the pyrites kiln are drawn into a condenser by means of a pump or any other arrangement, in order to free them from vapour and the dust; they then enter a leaden tower filled with coke, through which sulphuric acid of about 66° B. is kept constantly running. The gases are here completely dried. The mixture of sulphuric acid, nitrogen, and oxygen passes then into the combining furnace, which contains vertical iron retorts lined with a fire-resisting material, and filled with a contact substance. These retorts are kept at a temperature

between bright and dark red glow, and by means of the contact substance the gases  $\text{SO}_2 + \text{O}$  combine to anhydrous sulphuric acid, which is either condensed by itself, and then mixed with hydrated sulphuric acid, or passed into the latter. If the kiln gases contain carbonic oxide and hydrocarbons (which is the case when fuel has been used for the roasting of the minerals, etc.), a special combustion furnace is placed between the kiln and the drying tower, consisting of a retort kept at a red heat.—J. G.

## VIII.—GLASS, POTTERY, AND EARTHENWARE.

*On the Influence of Titanic Acid upon the Fusibility of Refractory Earths.* H. Seger, Dingl. Polyt. Journ. 83, 251, 1884.

IN the *Thonindustrie Zeitung*, 1883, 243, the author communicates the results of his experiments as to the variations in the fusibility of kaolin effected by the admixture of from 5 to 10 per cent. of silicic acid on the one hand, or of an equivalent amount of titanic acid upon the other hand. The method of conducting the experiment consisted in forming the mixture into little cones, and exposing it to a temperature between those at which wrought iron and platinum melt. Tested in this manner, the kaolin employed, which contained 1.5 per cent. of foreign substances, gave a white, hard mass of well-defined form, transparent at the edges and with dead surface. A mixture of 100 parts of kaolin with 5 parts of silicic acid produced a well-defined form, snow-white in colour, somewhat porous, transparent at the edges, and giving on fracture an appearance like that of porcelain. A mixture of 100 parts of kaolin with 10 parts of silicic acid behaved as the preceding, but gave a more porous product on fracture, still more closely resembling porcelain. The cone, composed of a mixture of 100 parts of kaolin with 6.65 parts of titanic acid, had, after heating, bent over to one side, and possessed a bluish-gray glazed surface, and proved, on fracture, to have thoroughly sintered together. The mixture of 100 parts of kaolin with 13.3 parts of titanic acid fused completely to a dark bluish-gray bead of enamel. It would thus appear that the presence of titanic acid has an influence exactly the reverse of that which silicic acid exerts, the conditions of temperature being the same. It therefore seems of importance to pay great attention to the amount of titanic acid present in earths to be employed as refractory materials. The author remarks that it is not impossible that the bluish-gray colour which some clays develop when very strongly burnt is due to the presence of titanic acid, as although this coloration is usually ascribed to the presence of iron, hitherto no relation has been established between the amount of iron and the presence or degree of this bluish-gray coloration.—W. D. B.

*A New or Improved Process for Enamelling Moulded Articles of Ceramic and other Refractory Materials.* C. D. Abel, London. Communicated by A. Schiebold, Plaut, Germany. Eng. Pat. 2964, June 14, 1883.

"ACCORDING to the present invention, ceramic articles, in particular statuettes, animals, flowers, or fruit, modelled in porcelain or earthenware, or in other suitable refractory materials, after being burnt or baked, are first coated or painted in the usual way with enamel colours of a syrupy consistency, and when this coating has dried somewhat, so as to be still sticky, it is thickly strewn over with small solid beads of transparent glass, which may or may not be coloured, and which adhere to the enamel coating. The moulded article is then heated in a muffle until the colours, as also the glass beads, have become sufficiently fused, whereby the ceramic article is provided with a coating consisting of the enamel colours combined with a peculiar refracting vitreous covering that imparts great brilliancy and freshness to the enamel colours, while the latter serve as a medium for uniting such vitreous coating effectually with the ceramic articles."

## X.—METALLURGY, MINING, Etc.

*Practical Results obtained from O. Springer's Double Puddling Furnace.* Dingl. Polyt. Journ. 250, 234, 1884.

EXCELLENT work has been obtained from O. Springer's double puddling furnace with regenerative firing, of which furnace a description may be found in Dingl. Polyt. Journ. 247, 329, 1883. At the works of Gebrüder Röchling, in Völklingen, 220 charges, each of 300 kilos, of raw iron were passed through both furnaces in eight shifts of twelve hours each—that is, an average of 13½ charges for each furnace per shift. The mean loss was 3.98 per cent., the consumption of fuel 56.90 per cent. One furnace therefore produced in the shift of twelve hours 3,960 kilos. of puddled blooms from 4,125 kilos. of pig iron, the consumption of coal amounting to 2,253 kilos. The raw iron was obtained exclusively from Minette ore—oolitic calcareous ironstone from Luxembourg—blown with reheating furnace slag. At the very best, the quality of the pig was only that of ordinary Luxembourg refined iron, and in many instances far worse. The coal employed was exceedingly poor and schistose, for it left from 50 to 70 per cent. of its own bulk of ash and cinder. The wrought iron obtained was of excellent quality and remarkably pure. The mechanical tests of the round iron of 25mm. diameter were as under: Breaking strain, (1) 37.58, (2) 38.46, (3) 37.65 kilos. per square millimetre; extension, (1) 24.2, (2) 25.6 per cent.; attenuation, (1) 36.6, (2) 43.0, (3) 43.1 per cent. It is apparent that the quality was such as to render this product specially suitable for horse-shoes, rivets, hoops, sheet iron, and tinplate. Taking into account the very poor quality of both the pig iron and of the coal employed for the production of the above, and not leaving the smallness of the amount of waste out of consideration, these results are extremely good. Should the experience of the working of Springer's furnace be the same on a large scale as above described, the puddling process cannot but undergo considerable modification.—W. D. B.

*The Manufacture of Tinplate.* Dingl. Polyt. Journ. 250, 231, 1884.

IN the *Sitzungsberichte des Vereins zur Beförderung des Gewerbfleißes*, in Berlin, F. Stoll sketches the processes adopted in the German tin plate industry. In the first place, several varieties of tinplate are distinguished according to the variety of sheet iron employed in their manufacture. These varieties are known as charcoal-plate, puddled-iron plate, coke plate, and steel plate. The first variety is still manufactured to a small extent from iron refined by wood charcoal. In the manufacture of puddled-iron plate great care must be taken in the selection of pig iron for the purpose. For coke plate, ordinary puddled iron is usually employed, since a better quality is not much in demand. Steel plate is manufactured from tough steel of different kinds. The so-called charcoal iron is obtained very hard and dense by refining pig iron and shot with wood charcoal. The tinplate made therefrom is difficult to work, but of great durability. To work the iron or steel into plates, blooms from the puddling furnace or refining hearth are flattened under steam hammers of 2,000 to 2,500 kgs. in weight, and rolled into thin rods, which are cut and made into bundles. The bundles are heated in a welding surface, thoroughly welded together, again heated in the same furnace, formed into bars by passing through grooved rolls, and cut into the size known to yield the finished plate of the required dimensions. The bars from the grooved rolls are formed into plates by passing through chilled rolls, and the plates are cut by machinery into the sizes known in commerce. By the above treatment the plates become so inflexible that previous to the polishing and cleaning process they require to be heated for from 10 to 15 hours in a well-closed muffle filled with plates. The flattening and polishing follow by passing the now softened plates between heavily-loaded chilled rolls. Before the tin can be expected properly to adhere, the plates require thorough cleansing from oxide. This is effected by the

action of dilute sulphuric or hydrochloric acid, followed by careful scouring with sharp sand. In the actual process of tinning there are five different stages. A series of five baths, with heating arrangement underneath, is built upon the same level. The baths are distinguished by the names of grease bath, tinning bath, brush bath, fine-tin bath, and grease or roll bath, the iron plate passing through the series in the same order as enumerated. In the first vessel the cleaned and scoured plate is covered with a film of melted tallow or palm oil, thence brought to the tinning vessel, freed from excess of tin at the surface by brushing with tow in the brush bath, immersed in the fourth or fine-tin bath, and, lastly, allowed to drain off any excess of metal either by standing in the final oil bath for a time, or by passing the now tinned plate through rolls fitted to this oil bath. The grease adhering to the surface at the termination of the process is removed by passing the plate through three or four boxes filled with slaked lime, sawdust, bran, or meal. The latter is the most economical in the end, as when the meal is saturated with grease it may be used as a cattle food. There now remains but the final polishing of the plate. This is effected by laying upon a table covered with flannel or sheep-skin, and rubbing the surface with a pad of the same materials. The finished plates are now sorted—reference being alone made as to their appearance—and branded as Prima-Blech (plate), W. Blech, and W. W. Blech, whilst those that appear at all defective are returned to be retinned. It has appeared desirable to do away with the oil baths, substituting baths of chloride of tin. Up to the present, however, the disadvantage of increased liability of the plates coated by the aid of chloride of tin to rust has not been overcome. W. D. B.

*On the Treatment of Rio Tinto Cupriferous Pyrites*  
Dingl. Polyt. Jour. 250, 82.

THE export ore, containing 3 to 3.5 per cent. of copper, is used, especially in England and Germany, by the vitriol maker, the roasted product being afterwards treated for silver and copper by well-known methods. Pyrites with 10 per cent. of copper is in some places roasted in heaps of about 200 tons, and charged, together with silicates and roasted copper slimes, into uniform closed hearth furnaces, 3m. high by 1m. broad and 1.2m. deep, yielding a marketable regulus containing some 40 per cent. of copper, the average daily charge worked through such a furnace being 30 tons of mixture with 16 per cent. of coke. Plumbiferous pyrites, with 5 to 7 per cent. of copper and 90grms. of silver per ton, is roasted in 200-ton heaps, and smelted with silicates in a shaft furnace, giving a regulus of 40 per cent. copper, and raw lead containing 60grms. to 90grms. of silver per ton. Pyrites with 1.5 to 2.0 per cent. of copper is roasted either in circular heaps 3.5m. high and 8m. in diameter, containing 200 tons, having a cross-shaped channel on the bottom formed by large pieces of ore and communicating with a central flue 0.3m. wide, or in 1,500-ton heaps, 17m. long by 10m. wide by 3.5m. high, with one channel running lengthwise and three transverse channels, and three flues (one at each intersection). Cavities are dug in the bottom between each two chambers (four, therefore, in the small and eight in the large heap), and in these fires of brushwood and old railway sleepers are maintained until the ore itself is burning well. The small heap will have burnt out in about two months with a consumption of 0.68c.m. of sleepers per ton of ore, the large heap in six months with 0.18 solid metre per ton. This small requirement of fuel is due to the easily inflammable nature and the rapid combustibility of the Rio Tinto pyrites and to the peculiar construction of the heaps, which favours an even and complete roasting. It is only with poor ores (1 to 2 per cent.) that the greater portion of the copper is rendered soluble by roasting. Richer ores must be subjected to a process of kernel roasting. By mixing the ore in small pieces with ferrous sulphate solution the formation of the copper sulphate in roasting is facilitated. The lixiviation of the roasted ore is conducted in tanks 30m. long by 10m. wide by 1.5m. deep. In the bottom, which slopes slightly downwards

towards one long side, are channels covered with a false bottom of planks, loosely laid, so as to permit filtration between them. In each of the lower corners of the tank is a taphole. The tapholes being closed, the tanks are filled with water to a height of a few centimetres above the ore. In about 10 hours this solution is drawn off and about ten times the quantity of fresh solution passed through, until no more copper is extracted. The solution containing 75 per cent. of the copper in the original ore passes through open channels into large reservoirs. The residue averaging 0.5 to 1.0 per cent. of copper is made whilst still moist, together with  $\frac{1}{2}$  to 1 part of rubbish, into heaps 3.5m. to 4m. high, provided with channels and flues. Heating rapidly takes place, and in six to eight weeks the freshly formed sulphate may be washed out. One and a half to two months later another washing takes place, and in 12 months the heap will be exhausted. The copper is precipitated in cemented and asphalted channels 1.5m. broad by 1m. deep, filled with pig iron. To these succeed shallower channels, also containing iron, in which the flow is more rapid. The solution must traverse 600m. of these channels in order to become decopperised. The copper is removed daily from the iron in the shallow passages by scraping with a blunt iron, from that in the deeper ones after draining. The cement copper so collected is drained in straw baskets, and carried in trucks to the roasting furnaces, where it is dried, heated, to remove part of the arsenic, cooled, and sold in sacks as oxide containing 70 to 75 per cent. Cu. The now copper free solution, after settling, is removed by pumps (composed of an alloy of Cu=80, Pb=15, Sn=5) to the extracting tanks where they are again serviceable for lixiviating. The slimes, after drying, are made into small flat cakes, air-dried, roasted in heaps, and melted with rich ore. The large consumption of iron in this process—viz., 2 parts to 1 part refined copper, or 140 parts to 100 parts cement copper—has led to precipitation by hydrogen sulphide (Dingl. Polyt. Jour., 164, 289) as in Hartmann's process. The solutions after precipitation, on account of the free acid contained, are advantageously used for a fresh extraction. Two experiments are being made at the Rio Tinto Works, with the Dötsch process, a method similar to those of Kopp and Chalandre. For this purpose, according to E. Cumenge and R. Wimmer (*Berg. u. Hutt. Zeit.*, 1883, 292), a pyrites averaging 2.68 per cent. of copper may be used without previous roasting. The copper is present as CuS and Cu<sub>2</sub>S. By treatment with ferric chloride solution it is decomposed by the equations—  

$$\text{CuS} + \text{Fe}_2\text{Cl}_6 = 2\text{FeCl}_2 + \text{CuCl}_2 + \text{S},$$

$$\text{Cu}_2\text{S} + \text{Fe}_2\text{Cl}_6 = 2\text{FeCl}_2 + \text{Cu}_2\text{Cl}_2 + \text{S}.$$

This solution, for which a mixture of ferric sulphate and common salt (yielding by double decomposition ferric chloride and sodium sulphate) may be substituted, will attack only the copper pyrites, leaving the iron pyrites untouched. The ore is mixed with 5 per cent. of common salt and an equal weight of ferric sulphate, and collected in heaps from 4m. to 5m. high. These are traversed with flues and channels of dried masonry, to establish currents of air. The ferric chloride solution is evenly distributed over the surface of the heap, through which it penetrates, passing out into a reservoir, where it settles, and from which it is conducted to the precipitating vessels. By methodical washing a 2.68 per cent. pyrites will in four months have lost half its copper, or 1.34 per cent., and in two years 2.2 per cent., while in the same time, by the old roasting process and lixiviation with pure water, only 1.1 per cent. would have been extracted. With extreme care 0.32 to 0.5 per cent., or even more, copper might be washed out in ten days, and the heap be exhausted in two years. The liquors, containing little else but chlorides of copper—and that to the extent of 5 to 7 kilos. per cubic meter—are precipitated with pieces of cast iron or old rails in long reservoirs 0.75m. deep by 2m. wide, lined with gypsum and asphalt or with Portland cement. Two years' observations have indicated a consumption of iron to the extent of 1.12 ton per ton of copper (against 1.56 to 1.7 ton by the old process). The copper precipitate contains 80 to 85 per cent. Cu. The solution after this treatment contains but 20grms. Cu per cubic metre, and may, after reconversion of the ferrous chloride into the ferric salt by means of chlorine, be again used

for extracting purposes. The chlorine is obtained by heating a mixture of ferric or ferrous sulphate and common salt in air in a reverberatory furnace, air being introduced through the fire bridge. In order to decompose any hydrochloric acid which might be formed, binoxide of manganese is introduced at the back of the furnace. The chlorine passes into a flue where it meets the ferrous solution as it trickles down and converts it into the ferric salt. A four months' trial, during which time 224 tons of 85 per cent. cement copper were made, gave the following figures relating to the cost per ton:—

Liciviation—	Marks.
0.62 tons sea salt for generating Cl <sup>and</sup> and mixing in heaps at 22 1/2m.....	13.65
0.2 tons sulphate of iron at 9 6m.....	2.10
Coal, pumping, labour .....	51.00
	67.05
Precipitation—	
1.12 tons iron consumed .....	83.20
Labour .....	61.60
	144.80
Sundries—	
Other materials.....	4.20
Improvements in reservoirs .....	9.50
Transport of machinery, etc.....	3.20
Maintenance of roads .....	0.96
Salaries, etc.....	1.58
	22.44
Total cost.....	231.29

Cost of working 1 ton of commercial copper = 276m.

The amount extracted in four months was 1.34 per cent., i.e., 1 ton of commercial copper from 75 tons of ore.

	Marks.
75 pyrites at 3.20m.....	240
Cost of working ditto as above .....	276
Transport to England, etc.....	24
	540

Total cost of 1 ton of copper..... 540

But these 75 tons of pyrites would in two years yield 1.65 tons of copper; this increase of 0.65 tons must be multiplied into the working cost (276m.) and the transport (24m.); so in two years 1.65 tons of copper will have been produced at a cost of 735m., i.e., at the rate of 440m. per ton. Taking copper at 1,300m. there is evidently a gain of 860m. per ton. The composition of a sample of cement copper prepared as above was—

Copper .....	51.90
Silver.....	2.35
Lead .....	1.45
Bismuth .....	4.95
Iron.....	7.00
Antimony .....	0.50
Arsenic.....	2.95
Sulphur.....	5.10
Lime .....	0.60
Sodium chloride .....	0.40
Sodium sulphate .....	1.40

Carbon (from cast iron) .....	0.40
Oxygen and loss .....	16.00
	100.00

W. G. M.

#### On the Production of Antimony and Zinc. Dingl. Polyt. Journ. 250, 123.

THE smelting of antimony is dealt with by R. Helmhaecker, in the *Berg. u. Hutt. Zeit.* 1883, 191. Antimony is nearly always obtained from antimonite ( $\text{Sb}_2\text{S}_3$ ), senarmontite ( $\text{Sb}_2\text{O}_3$ ) being found in workable quantities only in the Algerian provinces of Constantine. The liquation for crude antimony can be performed only on rich ores, those that are poorer retaining too much metal in the residue. For the crucible production of antimony, the sulphide may be fused with sodium carbonate, yielding metal and a sulpho salt, decomposable by acids to  $\text{Sb}_2\text{S}_5$ ; or the sulphide may be roasted and then mixed with raw sulphide, when a reaction occurs between them with the production of antimony and sulphur dioxide; but C. A. Hering (*Berg. u. Hutt. Zeit.* 394) remarks that this reaction does not take place unless reducing or other decomposing agents be present, the pure substances forming only glass of antimony. In the oldest process, raw sulphide is fused with scrap-iron. For smelting antimony ores in the reverberatory furnace, a solid hearth is indispensable, as the very fluid metal penetrates all crevices; and where no artificial bed is

ufficiently durable recourse must be had to granite or to some similar stone. This is formed into a trough of one piece, and must be made not from the hardest stone, which will probably crack on heating, but of softer, half-weathered varieties. Unroasted ore and scrap-iron may now be placed upon the furnace bed, where the former melts readily and is decomposed. All the metal cannot be thus recovered, since a part volatilises and a part forms a double sulphide with the iron. In the process

by which antimonite is fused with sodium carbonate, the mixture froths very considerably, and is found to attack the furnace. In the third process, the partially-roasted ore, containing  $\text{Sb}_2\text{S}_3$ ,  $\text{Sb}_2\text{O}_3$ , and  $\text{Sb}_2\text{O}_4$ , is charged into the furnace with small coal, scrap-iron, and soda (or with coal and soda alone). Where it is possible 8 to 13 per cent. of coal and 9 to 11 per cent. of soda are used without the addition of iron, since with the latter the slags are less fusible and do not

entirely cover the bath of metal, and a regulus rich in iron is also obtained (*Dingl. Polyt. Jour.* 162, 449). A furnace with a cavity on one of the longer sides, in which to collect regulus during the eliquation and the metal in the subsequent treatment, is best suited for this purpose. The great expenditure of fuel and loss by volatilisation in these processes render a method of smelting by the blast furnace desirable. Experiments in this direction have, however, at best, been only partially

satisfactory. Helmhaecker's early experiments failed, owing to the use of a coke with some 12 per cent. of ash and of powdered oxides of antimony. He therefore made up the oxide into lumps with 10 per cent. of sodium sulphate and a little water, and charged into the furnace with 33 per cent. of charcoal. At first all went well, the charges sank regularly down, a fine rain of metallic globules fell into the crucible, and a good red heat was maintained in front of the tuyeres; but in about six hours a quantity of blackish balls of slag (consisting of  $\text{Na}_2\text{S}$  reduced from the sulphate) accumulated before the tuyeres; and from that time the temperature gradually fell at this point.

The heat, however, was maintained, and the reduction still proceeded in the upper part of the furnace. About 150 to 200 kilos. of metal were tapped during this time, the metal flowing freely and solidifying with a dark gray rough surface. No slag whatever accompanied the metal, the cause of failure being the difficulty in finding a sufficiently fusible slag; otherwise the problem to reduce antimony in the blast furnace would appear to be solved. The composition of raw antimony varies with the method of production and treatment.

	I.	II.	III.	IV.
Antimony .....	91.5	81.0	97.2	95
Iron .....	3.0	10.0	2.5	4
Sulphur .....	2.0	5.0	0.2	0.75
Arsenic .....	0.25	1.0	0.1	0.25
Gold .....	Trace	..	..	..

I. and II. are analyses of metal made in the reverberatory furnace with iron scrap, the arsenic and gold resulting

from admixed pyrites; III. and IV. were from oxidised ores smelted in the blast furnace. Figures 1 to 4 represent ( $\frac{1}{20}$ th of actual size) an antimony refining furnace, which has been practically tested. The furnace is built of firebrick walls *z*, resting on ordinary brick *g*, the whole being braced together with iron rails in the usual way. Air is admitted by the channel *a* to the fire bridge. The fire door *v* may be at the side or at the end, as in Figs. 5 and 6. The working door *b* is of firebrick bound with hoop iron, and is most conveniently situated at the end in the principal axis of the furnace, but owing to its lying thus in the direct path of the furnace gases the workmen suffer much from the smoke, and it is therefore better at the side, as in Figs. 5 and 6. Here two doors

Fig 6

are used, the one *b* serving for the charging of the furnace and the lading of the refined metal, the other *c* for the withdrawal of slag. The bed of the furnace is constructed of one piece of hollowed granite, as described above. It stands free in the furnace, touching only the hindmost wall, and resting upon three iron wheels running on old iron rails *h*, let into the brickwork. At the deepest point in the bed is a hollow *l*, to facilitate the collection of the metal. The durability of the hearth varies greatly; some specimens crack when used for the first time, others may remain sound for a year. To avoid the expense of the granite hearths, the use of fireclay, stamped into the space between the furnace walls, has

been attempted; but although at first it is less expensive, it requires frequent renewing, since, from its greater porosity, it is more easily attacked by the soda than is the granite, and moreover it permits the metal to filter through it, and so to pass away through the walls into the ashpit. Where granite hearths are not available, the loss of metal by filtration may be obviated by stamping the fireclay into a riveted sheet-metal cylinder with ellipsoidal base (Figs. 5 and 6), which will thus retain any metal that penetrates the beds. A cheap

Fig. 7

material which will stand to a certain extent the action of the soda is yet to be found. Steatite and magnesite have been tried and have failed, the former owing to exfoliation by the heat, the latter by insufficient solidity. When the metal to be refined is very impure, it is treated with sodium carbonate and glass of antimony, otherwise with the latter only. To prepare the glass, the  $\text{Sb}_2\text{O}_3$ , which deposits as a thick white crystalline crust on the hotter parts of the flue, is melted with liquated antimony

sulphide, and thus forms a fusible glassy dark gray or brown mass. About 600 to 700 kilos. of raw antimony are placed on the bed of the furnace heated to a moderate cherry red, fumes of the very volatile trioxide pass away, together with a part of the arsenic, and in about 30 to 60 minutes the metal will have run down. From 3 to 7 per cent. (according to the purity of the metal) of sodium carbonate is now added, sometimes mixed with powdered coke or coal. A complete covering is thus formed to the metal bath, which then fumes less, and emits here and

there small jets of flame from the surface. The temperature is raised somewhat, and the metal allowed to remain under the melted soda for the space of one to three hours (a matter to be determined by experience), until the slag becomes somewhat thick, when it must be carefully and entirely removed by drawing through the working door by a transverse flat iron with a long iron handle. To remove the iron and last traces of sulphur 3 per cent. of  $\text{Sb}_2\text{S}_3$  and 1·5 per cent. of  $\text{Sb}_2\text{O}_3$  are thrown upon the surface of the tused metal, and when these have melted, 4·5 per cent. of potassium carbonate or of potassium-sodium carbonate is added. In, at most, a quarter of an hour the refining will be complete, and the workman must proceed to the critical operation of ladling. The ladle, which is of cast iron, in the form of a hollow hemisphere, and capable of carrying 15 to 20 kilos. of metal, is riveted to a long iron handle, and supported by a chain which hangs from the roof directly in front of the working door. The cast-iron moulds are arranged upon a stone table placed before the door. The workman must dip his ladle obliquely into the metal bath, so that he may withdraw a small quantity of the glass with the metal. Part of this glass must be carefully poured into the moulds first, in order to prevent actual contact of the antimony with the iron, and then every precaution must be taken that the former is throughout protected from the air as well as from the iron by a film of antimony glass. It is only by following out these details in every particular that good star-antimony can be obtained. The stellate appearance, which is accepted as a criterion of the purity of the metal in the market, will not occur if the surface be not completely covered with glass during cooling, or if the latter solidify before the metal. Moreover, if 'eyes' of unmixed alkaline carbonate rest upon the surface of the antimony they will prevent the formation of stars at that point. The slag can generally be used a second time and contains sulphides of antimony, iron and sodium, and oxides of antimony and iron, together with silica, etc., the percentage of antimony ranging from 20 to 60. The antimony trioxide, which deposits in the flues is admixed with soot and ashes from the fuel, and is removed from the condensing chambers as seldom as possible, because the men engaged in the work are subject to headache and sickness. The men at the refining furnace work in eight-hour shifts, and must be changed at least every week, since even in that time abscesses frequently form on the legs, breast, or neck. These, however, disappear with a change of work. The furnace such as described requires 600 kilos. of moderately good coal per 24 hours, and in that time will work off two or three heats, according to the purity of the raw metal. With the proportions of materials above stated, and allowing for a loss of 20 to 30 per cent. by slagging and volatilisation, the cost of refining regulus may be taken as four to five marks per 100 kilos. K. F. Föhr, in the *Berg. u. Hutt. Zeit.* 1883-4, treats of the Boëtius zinc furnace. Each furnace has two gas generators *a* (Figs. 7 and 8), the gases traversing half the length of the furnace, then passing down the channel *d*, and thence into the flues *c* placed between the muffles. The air necessary to combustion is obtained partly through *b* directly into the gas shaft, and in part through the passages *u* in the walls of the furnace. Thus the gases are partly burnt in the upper portion of the generator, but mainly in the furnace itself by means of the air channels *u*, which are fitted at their inlet with regulating screws, so that the furnace temperature may be under perfect control. The heat is thus evenly distributed, and the muffles are therefore not destroyed so frequently. To carry off the fumes, which are so annoying to the workmen, a flue *k* passes along the top of the furnace connected with the hood of each pair of muffles. At the Lipine works, in Silesia, a movable iron hood connected with an iron flue passing just through the roof serves the same purpose, but is useless when the wind is high and causes a down draught. Glazed muffles have been used at some works, but the ordinary form is generally adopted. These cost four or five marks apiece, with an average life of 32·3 days. Dagner's condenser (*Dingl. Pol. Journ.* 236, 486), has been tried at several

works in Silesia, but the yield of metal does not appear to have been finally increased, though more oxide is obtained. The originally-increased yield gradually became less as the condensers became older and cracked, until at last it was but little greater than by the original method. One advantage of this system lies in the fact that the nozzles need not be removed in order to ladle the zinc. Cylindrical upright nozzles, as at the Hohenlohe works, collect a larger portion of the dust and oxide than those generally used, and when employed in conjunction with Dagner's condenser no zinc flame appears at the orifice, and the gases pass out through a conical nozzle on the side nearest to the furnace, and thus are far removed from the workman. A flap valve at the bottom of the nozzle allows the zinc-dust to be removed from time to time.—W. G. M.

*On the Use of Nickel-plated Cooking Utensils.* H. Schulz, *Dingl. Polyt. Journ.* 250, 421.

THE author considers that the use of such vessels with acid fruits and the like is not quite so dangerous as Birnbaum has indicated (*Dingl. Polyt. Journ.* 249, 515, and 564). A dog, fed for twenty-nine days with rabbits which had been killed by poisonous doses of nickel, and having, in addition, 0·5grm. per diem of nickel acetate mixed with his food, was, with the exception of slight diarrhoea, commencing on the fifth day and lasting for four days, and a gradual loss of appetite, perfectly well throughout, and at the end of the time had increased in weight by 1·230grms. Broadbent has found that nickel chloride in quantities of over 0·18gr. induces vomiting. Rabbits weighing from 2 to 2·5 kilos. can take 0·5grm. of nickel acetate *once* with impunity, but 1grm. has always proved to be a fatal dose. Injected into the blood, nickel salts act as a violent poison—they possess fairly active antiseptic properties. In doubtful cases, however, the author thinks that not nickelised vessels might be used.—W. G. M.

*On the Examination of Iron and Steel.* *Dingl. Polyt. Journ.*, 250, 413.

EXPERIMENTS by Sir F. A. Abel and W. Deering on the condition in which carbon exists in steel were reported in the *Journ. Chem. Soc.* 1883, 303. Discs of cold-rolled steel rod, originally yielding 1·108 per cent of carbon (uncombined = 0·096 per cent.) were found after hardening to yield 1·128 per cent. (uncombined = 0·035), and after annealing only 0·92 to 0·86 per cent. (uncombined = 0·052). By treatment with a solution of 99grms. of potassium bichromate and 90 of sulphuric acid per litre, a black magnetic residue—corresponding to the formula  $\text{C}_3\text{Fe}_6$ —was left. It contained nearly the whole of the carbon from the cold-rolled and the annealed samples, but only one-sixth of that from the hardened specimen. Similarly, plates from cementation steel yielded a residue of 13·25 per cent. of a carbide of iron in which the ratio between the elements was 1 atom C. : 2·65 atoms Fe. A weak solution of chromic acid gave 14·16, and a strong solution only 4·66 per cent. of the carbide. It would appear that in cold-rolled and in annealed steel carbon exists as  $\text{Fe}_3\text{C}$ , but this compound is so altered by the hardening process that it is readily attacked by chromic acid. V. Eggertz (*Berg. u. Hutt. Zeit.* 1883, 435), in writing concerning the colorimetric estimation of carbon in iron, points out that in working with artificial standard solutions the temperature of both tubes should be the same, namely, 18°, since at a higher temperature the standard appears darker than the corresponding iron solution, and this to so marked an extent that a steel which, *e.g.*, gives 1 per cent. of carbon at 18°, shows only about 0·85 at 25°. The tubes should therefore be brought to the required temperature by immersing in water at 18°. To obtain a standard steel of uniform composition, the surface of the sample must be planed or turned off. It will have lost carbon in the operations to which it has been subjected. If the standard steel approximates to 1 per cent. of carbon, clean saw files should be used for preparing the sample, as these in their hardened condition usually contain 1 per cent. and therefore there

is but slight cause for fear that the apparent composition of the specimen will be altered by the wearing of the file itself. Having once obtained a solution containing 0.1 per cent. of carbon per cubic centimetre, any desired standard may be obtained by accurate dilution. By means of this normal solution (1 c.c. = 0.01 c.) pig-iron containing over 4 per cent. of combined carbon may be treated, and will yield results within 0.1 per cent. In this case 0.05 grm. of metal should be used—it must be weighed with extreme accuracy. E. Raimond (*Revue Univ.* 1883, 460) estimates volumetrically the manganese in iron, steel, and ferro-manganese, by dissolving 3 grms. of the substance in 40 c.c. of hydrochloric acid (sp. gr. = 1.40) removing from the flame, adding 15 grms. of potassium chlorate and 20 c.c. of nitric acid (sp. gr. 1.4), digesting for a quarter of an hour until excess of chlorine is removed, and collecting the manganese-dioxide upon a filter. After washing with hot water it is retransferred to the flask in which the precipitation was effected, and into which has been introduced 50 c.c. of a solution containing 45 grms. of ferrous sulphate, to 750 of water and 250 of sulphuric acid. The reaction expressed by the equation—

then sets in, and the residual ferrous sulphate is titrated with potassium permanganate. The filtrate may be used for the molybdate of ammonia phosphorus determination. Troilius (*Berg. u. Hütt. Zeit.* 1883, 255) proposes to estimate manganese by dissolving the iron in hydrochloric acid, evaporating to dryness, digesting with nitric acid of sp. gr. 1.35 to 1.40, and precipitating with potassium chlorate. The precipitate is collected with the aid of a Bünsen pump on asbestos, washed with the strong nitric acid, and afterwards with water. It is then to be transferred to a beaker, dissolved in warm hydrochloric acid, filtered from the admixed asbestos, and heated until the last trace of free chlorine has vanished. The small quantity of iron, which was present in the precipitate is removed by ammonia and ammonium acetate. The filtrate is then made strongly alkaline with 0.88 ammonia, and precipitated with 1 grm. of 4 grms. of bromine, stirred to aggregate the precipitate, brought slowly to the boil, maintained at 100° for an hour, filtered, and weighed as  $\text{Mn}_2\text{O}_3$ . It is essential that the nitric acid used be very strong. If ordinary or diluted acid be employed with an excess of potassium chlorate, some permanganate will be formed. T. Morell's method of estimating iron is as follows: The weight of substance taken should contain about 0.2 grm. of iron when in solution as perchloride. The solution must be free from all bodies which liberate iodine from potassium iodide. It is introduced into a long-necked flask of about 300 c.c. capacity, and provided at the side with a tubulated aperture accurately stoppered, 2 grms. to 4 grms. of potassium iodide are added, and the necks closed with well-ground stoppers. The flask is then heated to 60° for a few minutes, and again completely cooled, when a weighed quantity of mercury is introduced, and the flask agitated violently in a current of carbonic acid until the solution is quite colourless. The solution is then poured off through the side tube, and the mercury washed repeatedly with water. Finally, the mercury itself is transferred to a porcelain crucible, dried with blotting paper, and weighed. The loss of weight indicates the amount of iron with the aid of the equations—

so that one part of dissolved mercury is equivalent to 0.56 parts of iron. A. Tamm (*Jern Kontoret's Ann.* 1883, 74) determines the phosphorus in iron by the following methods: 1 grm. of the metal is dissolved on the hot plate in 12 c.c. of nitric acid (sp. gr. 1.2) and evaporated to dryness. It is then heated to 200° for an hour and treated with 6 c.c. of hydrochloric acid (sp. gr. 1.19), and again heated to 200°. After redissolving in hydrochloric acid and removing the excess of acid, it is diluted with 5 c.c. of water, and is ready for precipitation with ammonium molybdate. Or 1 grm. is dissolved as before, but not heated above 100°, the residue being taken up in 3 c.c. of hydrochloric

acid with 2 c.c. of nitric acid. This second method gives, when metal is treated, a lower percentage of phosphorus than the former. Tamm attributes this to the solvent action upon the phospho-molybdic precipitate of organic acids formed by the action of the nitric acid upon the combined carbon, and which are decomposed at a temperature of 200°. This view would appear to be strengthened by the fact that iron ores give the same results by both methods. V. Eggertz (*Berg. u. Hütt. Zeit.* 1883, 353), in writing of his process for determining phosphorus in iron, discusses the possibility that the phosphorus, which is not precipitated by the molybdate, is present as a new variety of phosphoric acid. If it were meta- or pyro-phosphoric acid it would be converted by boiling nitric acid into the ortho condition. But this variety is apparently unchanged after boiling with nitric acid of specific gravity 1.3 and with strong hydrochloric acid. Even then precipitation will not take place. It may, however, be converted into the desired modification by causing it to unite with ferric oxide or the basic salt formed by drying the evaporated iron solution at high temperatures; and it is recommended to employ a temperature above 200°. By simple solution of the iron in nitric acid three-fourths of the phosphorus present is converted into ortho-phosphoric acid, and one quarter into the new form. Hence accurate results may be obtained with samples, not containing too large an excess of carbon and silicon, by boiling the acid solution for some time, without evaporation, and multiplying the weight of the molybdate precipitate by  $\frac{1}{4}$ . It must be remembered that samples of iron containing slag will give, on analysis, the phosphorus contained in the latter (which cannot influence the quality of the metal), in addition to that present in the iron itself. In such a case the metal may be treated with bromine, which leaves the slag unacted upon. The solution after filtration is acidified with hydrochloric acid, evaporated, dried at 200°, and the phosphorus precipitated in the usual way. The drying of the yellow precipitate is facilitated by employing a temperature of 110° to 112° instead of 95° to 100°; but the percentage of phosphorus contained must then be taken as 1.64 instead of 1.63. In dealing with ores, the results obtained after drying at 100° are equal to those resulting from the use of a higher temperature. But inasmuch as many ores contain phosphorus in the form of insoluble compounds, it may be necessary to submit them to fusion with sodium carbonate; or they may be reduced in a crucible, and the phosphorus determined in the resulting metal, since it is found that nearly the whole of the phosphorus passes into the iron under those conditions. So also in estimating sulphur, if it be present as barium sulphate, this body being insoluble, the analysis will give too low a result, but by the reduction process the sulphur will pass into the iron. When the silver plate becomes blue, owing to the presence of a large amount of sulphur, the method is not accurate. But at the same time it suffices to prove that the iron is useless for most purposes.—W. G. M.

#### Yellow and Red Oxide of Lead. A. Geuther. *Annalen* 219, 56.

By heating red oxide of lead (chrysolite, goldglätte) to its fusing point it is resolved into the yellow oxide (argyrite, silberglätte). A similar result is obtained when the salts of lead, which lose their acids at this temperature, are heated, e.g., the carbonates and nitrates. The resulting yellow oxide, after fusion and rapid cooling, solidifies into a mass of crystalline laminae. By fusing the hydrate with potassium hydroxide, and quickly cooling, the yellow oxide is obtained in a crystalline state. Likewise by introducing a boiling solution of a lead salt into boiling soda ley ( $\text{1Na}_2\text{O} + 5\text{H}_2\text{O}$ ) or hot milk of lime. Large transparent lamellar crystals, of fine lustre and yellow colour, are formed, by adding to a boiling solution, consisting of 7 parts potassium hydroxide and 14 parts of water (boiling point 110°), 1 part of finely-pulverised hydrated oxide of lead. The mixture is kept at this temperature until nearly all the lead has been dissolved, after which the solution is allowed to cool gradually. The formation of a red-coloured oxide of

lead from the hydrate begins at  $110^{\circ}$ , and in order to complete the same it is necessary to raise the temperature to  $150^{\circ}$ , and conduct the heating in a closed crucible. For the conversion of the carbonate into the red oxide a high temperature is required. To obtain the red oxide in the form of lamellar garnet-red crystals it is recommended to dissolve 1 part of the hydrate in 5 parts fused potassium hydroxide and slowly cool the mixture. By boiling the hydrate in a solution of 3 parts sodium hydroxide and 4 parts water (boiling point  $130^{\circ}$ ), red crystalline hydrated oxide of lead is obtained. The yellow oxide has a specific gravity of 9.28 to 9.36, the red 8.74 to 9.126. The former crystallises in rhombs, the latter in a tetragonal form. It is further shown that at the ordinary temperature the yellow oxide may be resolved into the red by pressure and friction, whilst to convert the red oxide into the yellow it is necessary to heat the same almost to the fusing point. By fusing the oxide with potassium hydroxide in atmospheric oxygen a compound of peroxide of lead and potash is deposited, on cooling, in the form of light-brown six-sided tables.—D. B.

*The Dephosphorisation of Iron.* Dingl. Polyt. Journ. 330, 250, 1884.

As communicated by him to *Stahl und Eisen*, 1883, 498, G. Hilgenstock has observed that a crystalline formation takes place at times in the slags obtained in the dephosphorisation of iron by the basic process. He has isolated such crystals as carefully as possible, and has found them to possess the percentage composition of 61.10 CaO, 38.14  $P_2O_5$ , corresponding to the formula for tetra-basic calcium phosphate,  $Ca_4P_2O_{10}$ . This occurrence of the tetra-basic phosphate explains, to some degree, the necessity for the comparatively large amount of lime in the basic process. Carnot and Richarl, in the *Revue Industrielle*, 1883, 365, record the occurrence of transparent blue crystals in the cavities of a basic slag from Jonef. The crystals were found to correspond in their composition to that of a silico-phosphate of calcium, together with small quantities of ferrous oxide and alumina. The analytical results are as under—

$P_2O_5$ .....	29.65
$SiO_2$ .....	12.12
$Al_2O_3$ .....	2.76

W. D. B.

*An Improved Process and Method for Making Refined Cast Steel from Inferior Wrought Iron, as well as the Best Quality of Wrought Iron.* T. Sheehan, London. Eng. Pat. 2862, June 8, 1883.

TREATMENT of "inferior wrought iron" by, per 20 tons thereof, 110lb. of "muriate of soda," 80lb. carbonate of soda, 70lb. bisulphate of soda, 40lb. sulphite of zinc, and 6 bushels of hardwood charcoal, together with alumina and "granular limestone."

*An Improved Process of Treating Lead to Impart to it the Property of Adhering to and Amalgamating with other Metals.* P. M. Justice, London. Communicated by F. J. Clauer, Philadelphia, U.S.A. Eng. Pat. 3933, Aug. 14, 1883.

"THE object of this invention is to treat melted lead" in such wise as to "so change the nature of the metal that, by a process similar to galvanising with zinc, the surfaces of iron, copper, brass, etc., may be covered with a smooth and permanent coating of lead, free from holes, and not liable to scale off." The "small holes and blisters so frequently found in" the coating of "a sheet of metal coated with lead in the ordinary way," are attributed to the molten lead absorbing gases, which are given out on cooling. "Melted lead is also thick and sluggish, consequently a coating formed in the usual way is full of ridges, the metal being very unevenly

distributed over the surface of the sheet." By adding to 100 pounds of molten lead "first three ounces of sal ammoniac, then half an ounce of arsenic, after this one ounce of phosphorus, and lastly half an ounce of borax," the lead is said to have all gases driven out of it and to be rendered limpid, with the result that sheets or other articles of iron, copper, or brass, dipped into a bath of it, become coated with it perfectly evenly.

*An Improvement or Improvements in the Manufacture of Alloys of Tungsten.* F. W. Martino, Shetfield. Eng. Pat. 3421. July 11, 1883.

OWING to the very high fusing point of tungsten, it is not practicable to form alloys of that metal with metals which fuse at very much lower temperatures, by melting it and them together. The author of this invention obtains alloys of tungsten with copper, tin, and zinc as follows: "I take a mixture of metallic tungsten and phosphide of calcium and fuse the mixture in a crucible, preferably a plumbago crucible. I keep the crucible well covered with a lid, and the contents of the crucible covered with a layer of powdered charcoal, during the fusion of the mixture of tungsten and phosphide of calcium. By the action of the phosphide of calcium on the tungsten, a regulus of phosphide of tungsten is produced. I add this phosphide of tungsten to metallic copper or to phosphor bronze and melt the mixture in a plumbago crucible, the mixture being covered with a layer of powdered charcoal. In this way I obtain an alloy of tungsten and copper, the said alloy also containing phosphorus. By the addition to this alloy of tungsten, copper, and phosphorus of an alloy of copper and tin or copper and zinc, I produce a series of alloys having such colours and possessing such ductility and malleability as fit them for the manufacture of a variety of articles, such, for example, as spoons, forks, fish and dessert knives, as well as vessels of various kinds."

*Improvements in the Treatment of Compounds of Aluminium for the Purpose of Obtaining therefrom Aluminium or Aluminium Bronze, and in the Means Employed in the said Treatment.* J. H. Johnson, London. Eng. Pat. 2888, June 9, 1883. Communicated by J. Varin, Paris. Not proceeded with.

THE author of this invention proposes to electrolyse fused double chloride of aluminium and sodium, using as negative electrodes either retort charcoal or aluminium plates, and as positive electrodes plates of "an intimate mixture of alumina and carbon." The chlorine evolved at the positive electrode is to combine with the aluminium of the alumina of these electrodes, forming aluminium chloride, by which to continually replenish the bath, and the oxygen of their alumina is to combine with their carbon, and so to be evolved as carbonic oxide.

*Improvements in the Method or Process of Treating Ores and Substances containing Antimony and other Metals for the Recovery thereof.* J. C. Butterfield, Westminster. Eng. Pat. 2945, June 13, 1883. Not proceeded with.

ANTIMONY ore is to be reduced to an impalpable powder, and then boiled, with frequent stirring, with a solution of ferric chloride of  $70^{\circ}$  T. "The perchloride of iron is reduced by the antimonous sulphide, whilst the antimony is dissolved as chloride, with separation of sulphur." From the solution of antimony chloride thus obtained, free antimony is then precipitated by scrap iron.

*Improvements in the Treatment of Tin and Terne Plates.* D. Grey, Maesteg, Glamorgan. Eng. Pat. 2874, June 8, 1883.

THIS invention consists in substituting for the palm oil at present used by manufacturers of tin plates various mixtures of linseed, resin, Rangoon, castor, and cotton oils, and especially a mixture of linseed oil and resin oil, in the proportion of 65 parts of the former to 35 parts of the latter.

## XI.—FATS, OILS, AND SOAP MANUFACTURE.

*Cotton-Seed and Palm-Nut Oils.* Seifensied. Zeit. 33, 390.

ON account of the high price of tallow, these oils are almost indispensable to the soap manufacturer. Both oils are commonly used together for making hard soaps, cotton-seed oil being particularly useful in summer, on account of the large proportion of stearin (about 30 per cent.) it contains, which renders the soap more compact and capable of withstanding the action of higher temperatures. Crude cotton-seed oil has a reddish-brown colour, and when intended for exportation is usually treated with soda. The oil thus refined has a density of 0.926, and solidifies at about  $2\frac{1}{2}^{\circ}\text{C}$ . During late years cotton-seed oil has been extensively used for the adulteration of olive oil. Palm-nut oil is obtained from the palm-nut, either by pressure or extraction with carbon disulphide or light petroleum, the latter being preferable, as carbon disulphide, when not perfectly eliminated from the oil, causes serious trouble, giving both a bad smell and colour to the soap made from it. Palm-nut oil is seldom used by itself for soapmaking, as it produces a very brittle and easily-cracked soap, which combines with but little water, and thus causes the produce to be very low. Palm-nut oil is, however, of importance when mixed with other fats. In order to free ordinary refined cotton-seed oil from colouring matter it is treated with the entire quantity of ley, at  $24^{\circ}\text{Baumé}$ , required for the complete saponification of the fats to be used, and the mixture boiled. The other fats are now added, and, after addition of water, the saponification, which has not yet entirely taken place, is completed.—A. H. A.

*Neutral Soaps, for Soaping Coloured Goods.* Chem.-techn. Centr. Anz., Seifensied. Zeit. 34, 405.

IT is known that a soap is required for brightening the colour of garancin, or artificial alizarin, on printed goods, without causing change or injury. Marseilles-soap is given the preference without any clear idea of what constitutes the difference between the various soaps. O. Scheurer, in the *Bulletin de Mulhouse*, says that when the soap acts on the colour, as is especially the case with olein soap, it is because the soap has been insufficiently saponified, part of the oil used being undecomposed, and free alkali (which does the mischief) left in solution, causing the reds to turn brown, injuring the violets, and spoiling the whites. He points out that although the proper quantity of alkali may be present, if the boiling of the soap is not continued sufficiently long the result will be an alkaline soap. Increased temperature and pressure very much hasten the formation of a neutral soap. Boiling for two hours, under a pressure of  $1\frac{1}{2}$  atmosphere, gives a better soap than twelve hours under the ordinary atmospheric pressure.—A. H. A.

*Fat and Grease of the Chinese Tallow-Tree.* Techniker, Seifensied. Zeit. 35, 415.

THE high price of tallow of animal origin has caused the attention of soap and candle manufacturers to be turned to vegetable fats. The tallow-tree is a native of China. It produces a fruit of which the kernel is covered with a thick layer of tallow, and contains yellowish aromatic oil, useful for heating purposes. After the fruit has been gathered, which is done in South China in July, and in the North in October, hot water is poured over it. When the water has cooled, the tallow can be taken off. It is then run into bamboo-cane moulds ready for the market. It has a green colour, crystalline structure, possesses a characteristic smell, and melts at  $40^{\circ}$ .—A. H. A.

*A Method of Freeing Tallow from the Smell of Petroleum.* Seifensied. Zeit. 39-462.

IN Germany, tallow, treated with 2 per cent. of petroleum oil, is free from duty. The writer gives the following method of freeing it from the objectionable smell of the

petroleum. The sample is placed in a cauldron, and for every 100 pounds weight about half a pound of zinc chloride, dissolved in water, is added. Steam is now passed through the liquid for from two to three hours. Instead of steam, the sample may be well boiled with a fourth of water for the same length of time.—A. H. A.

*Russian Mineral Machine Oils.* "Bakuin." By a Foreman of A. Oehlrich and Company, Riga. Seifensied. Zeit. 31, 366; 32, 375.

VARIOUS brands of oil are made corresponding to the different viscosities required in lubricants. Two qualities, known as Bakuin 1A 1A and Bakuin AA have respective densities of 0.910 and 0.905. These oils are recommended for lubricating heavy machinery, on account of their high viscosity and great power of resisting cold. The Bakuin oils generally are said to be greatly more economical than vegetable oils, and to freeze less readily. Astralin is a burning oil, which can be used in ordinary petroleum lamps, and it is said to be less inflammable and to be consumed more slowly than petroleum.—A. H. A.

*Improvements in the Method of Treating Linseed and other Drying Oils, so as the better to fit them for Use in the Arts and Manufactures.* A. Ford, London. Eng. Pat. 3193, June 27, 1883. Not proceeded with.

THE linseed or other oil treated by this invention is heated to from  $130^{\circ}$  to  $150^{\circ}\text{F}$ .; solution of diacetate of lead is added to it, and into the mixture air is injected, during 10 hours. The mixture is then allowed to settle, the "foots or settlings" are separated, and on the clear part the above-described treatment is repeated, "only at a much lower temperature" than the first time. The product is said to possess "such drying powers" that paints made with it need not be mixed with "turpentine or other dryers."

## XII.—PAINTS, VARNISHES, AND RESINS.

*An Improvement in the Manufacture of Anti-fouling Paints or Compositions.* A. M. Clark, London. Communicated by C. Dubois, Marseilles. Eng. Pat. 3320, July 4, 1883.

"THIS invention consists in the combined employment of the sulpho-cyanides of copper and the arseniates of mercury in any kind of paint for marine purposes."

## XIII.—TANNING, LEATHER, GLUE, AND SIZE.

*Tannins of Oak Bark.* C. Etti. Monatsch. f. Chem. 40, 512.

THIS is a critical comparison of the author's results with those of Böttger and Löwe. The following is an outline of his main conclusions. The tannic acid of the oak bark occurs both as the body ( $\text{C}_7\text{H}_6\text{O}_5$ ), and as its first or semi-hydrate ( $\text{C}_7\text{H}_8\text{O}_7$ ), which latter constitutes the phlobaphene of the bark. On boiling this semi-hydrate with dilute sulphuric acid the second anhydride, ( $\text{C}_7\text{H}_4\text{O}_6$ ), is formed. The original tannic acid, on the other hand, yields, on boiling with the acid, the third anhydride ( $\text{C}_7\text{H}_2\text{O}_8$ ). The fourth anhydride ( $\text{C}_7\text{H}_4\text{O}_{10}$ ), was obtained by Löwe by heating the original tannic acid with either water or dilute sulphuric acid at  $110^{\circ}$  for eight days. Various compounds described by Oser, Grabowski, and the above authors are severally identified with these bodies, and thus a number of discrepancies are cleared up. In the isolation of the original tannic acid special regard must be had to the first of these anhydrides, which, in addition to being likewise present in the bark, is formed from the tannic acid in the course of its separation by means of solution in acetic ether. This acid, in fact, decomposes the acetic ether, and the resulting acetic acid exerts a dehydrating action upon the tannic acid. The author, therefore, in the last stage of purification uses ether-alcohol as the solvent. In addition to this phlobaphene, the crude tannic acid contains a terpene resin, which is easily eliminated by taking advantage of

its solubility in benzene. The sugar obtained by certain observers on boiling the tannic acid with dilute mineral acids is shown to result from the levulin present in the bark. From the number and mode of formation of the above anhydrides, together with the evolution of methyl chloride on heating the tannic acid with hydrochloric acid, the author concludes that it is a methyl derivative of a gallylgallic acid,  $C_{40}H_{32}(ON)_{12}.CO.C_6H_5N(ON)_2COON$ . The author has also investigated a tannic acid ( $C_{20}H_{16}O_8$ ) obtained from the bark of a different species of oak. This tannin gives a green colour with ferric chloride, but in other respects was closely similar to the tannic acid described above. Thus it yielded four successive anhydrides—

under conditions of dehydration exactly resembling those employed with the previous acid. On subjecting the acid to dry distillation there were obtained from 1,500 grms. 4grms. pyrocatechol, 800grms. of the pseudo-carbon, and 2.6grms. of an oil, apparently a terpene, and derived from the resinous impurity of the acid. On heating the acid with hydrochloric acid very little methyl chloride was formed, whence the presence of oxalcoholic groups was to be inferred. The reactions of the acid otherwise point to a similar deviation from a gallylgallic acid—

Lastly, the author suggests that the phenols and phenol-ethers present in wood tar are probably formed at the

finally be evaporated *in vacuo* to a density of 20° B. If it be desired to remove mucilaginous matter as well as colouring matter, four times the above-mentioned proportion of alumina must be used.

#### XIV.—AGRICULTURE, MANURES, Etc.

*On the Superphosphate from Animal Charcoal.* Prof. Fr. Farsky. Biedermann's Central-blatt. für Agrikulturchemie, 12, 449. Bericht der landw-chemischen Versuchsstation in Tabor für das Jahr, 1881 and 1882.

PREVIOUS investigations by the author had proved that the Bohemian superphosphate from animal charcoal prepared in different works contained free phosphoric and sulphuric acids and dicalcium phosphate, besides the chief constituents, monocalcium phosphate and calcium sulphate. Free sulphuric acid was only found in superphosphates which contained no tricalcium phosphate, or in poor products prepared by the admixture of richer ones with earth. Its amount ranged from 0.1305 to 1.0548 per cent. Monocalcium phosphate was found in superphosphates which had contained more than 1 per cent. of tricalcium phosphate, and in such as had been mixed with clay, lime, or calcareous earth. Calculated as phosphoric acid, it amounted to 0.0241–1.9417 per cent. Free phosphoric acid was only detected in rich products to which too much acid had been added. Coarse-grained superphosphate contained more free acids than fine ones. The amount varied from 0.2452 to 2.5000 per cent. It

expense of a tannic acid, having a constitution represented, at least in its main outlines, by one of the following formulæ—

*Improvements in the Preparation of Tannic Extracts.* J. R. Johnson, London. Communicated by E. L. P. Coëz and G. C. Coëz, St. Denis, France. Eng. Pat. 3150. June 26, 1883.

THE "tannic extracts heretofore supplied to tanners are to a certain extent rendered colourless by various processes," but these are processes by which "the colouring matter" of the extracts is "merely neutralised by chemical agents," leaving it "liable to reappear at any time under certain conditions, such as age or exposure to the air." By the present invention, the colouring matter is to be removed, instead of simply neutralised. To this end, to tannic extracts "obtained by the usual processes" oxalic acid is added, in the proportion of 1grm. to 100 litres of decoction, "for the purpose of saturating the lime of the water used in the process of extraction." Then gelatinous alumina is added, in the proportion of 250grms. per 100 litres of decoction. The alumina combines with the colouring matter present, and filtration now yields a "clear tannic extract," which must

appear that excess of acid decomposes the monocalcium phosphate with formation of dicalcium phosphate and free phosphoric acid. The author concludes that better results are obtained by the acidification of fine than of coarse raw material, and that free acid is not so likely to occur when the acid is poured on the animal charcoal as when that substance is added to the acid. *Action of Water on Superphosphates:* A sample of superphosphate was separated by a sieve into two portions. The coarser contained 11.6, the finer 10.26 per cent. of soluble phosphoric acid, but no dicalcium phosphate. The substance was placed in vessels with finely-porous bottoms, which stood in other vessels. In most cases 2–4, and later 1.2–2.4c.c. of cold water were sprinkled on the different portions. Two samples were allowed to dry, and several were not moistened at all. The latter remained entirely unaltered, while the others were acted on as above. Thus by moistening the superphosphate and allowing it to stand in the air, soluble phosphoric acid is lost. The nature of the reaction is indicated by the results tabulated below:—

Water added.	Amount of Products formed in Percentages of the Original Phosphoric Acid				
	as $CaH_4(PO)_2$	as $CaHPO_4$	as free acid	washed out	decomposed
Little	52.30	23.86	23.84	—	47.40
More	50.13	24.94	18.11	6.82	49.87
More	—	30.33	—	12.21	—
More	—	37.75	—	11.22	—

The mono-calcium phosphate is thus decomposed with formation of free acid and the dicalcium salt. The above results show clearly why, in the analysis of superphosphates, the samples must be treated at once with plenty of water, otherwise the percentage found would be too low. *Behaviour of Superphosphates in Moist Earth:* Every 100grms. of earth containing 7.78 per cent. of calcium carbonate and 0.12 of tricalcium phosphate were mixed with 10 grms. of 12.3 per cent. fine, or with 8.8489grms. of 13.9 per cent. coarse superphosphate, and sprinkled repeatedly with 5 or 10c.c. of water. The residual soluble phosphoric acid was estimated from time to time with the following results:—

becomes insoluble. (3) The retrogression of finer grained superphosphates is at first more rapid than that of coarser, but here, again, the difference becomes gradually smaller. (4) Since the germination of moist seeds in the earth occupies from seven to fourteen days, it follows that in calcareous earths the plants obtain their phosphorus chiefly, if not solely, in the form of the calcium phosphate soluble in citric acid. *Experiments under Glass:* Several vessels 65c.m. high, and of 1,000 square cubic centimetres surface, were filled with earth of known composition, which had been mixed with 20 per cent. of calcium carbonate. The plant employed was the Tartary buckwheat. It was sowed thickly at first, and

Thus the retrogression of the superphosphate in the earth was very rapid. It was found by analysis that acid aluminium and iron phosphates were formed by the action of the free acid on the alumina and iron compounds. They are, however, unstable, and had almost disappeared by the sixth day. The presence of free acid was ascertained by further experiments. The acid is

then weeded. The results are given in the table below. From these results the author concludes: (1) That the plants are developed more regularly, and that the crop is greater when the superphosphate is strewn by hand, than when it is previously mixed with earth. (2) That the best result is obtained when the manure is placed below the seeds. (3) That the action of the super-

rapidly neutralised by the excess of salts in the earth, forming mono-calcium phosphate, and this in turn is acted on by the calcium carbonate forming dicalcium phosphate. The results may be summed up as follows: (1) The larger the quantity of calcium carbonate in the earth the more rapid is the retrogression of the superphosphate. The action is brought about by water. (2) The more water circulates in the earth the smaller is the retrogression and *vice versa*. The difference decreases, however, in proportion as the soluble phosphoric acid

phosphate is more satisfactory in clayey than in calcareous earths. The retrogression of the coarser superphosphate was again found to be slower than that of the finer. Further experiments showed that it would be better, if practicable, to add the manure after the germination of the seeds than before. A regulated amount of moisture is also seen to be of importance to the plants. The author finally concludes from a repetition of three experiments (1) That the coarser superphosphate acts more beneficially than the finer, and (2) that a larger

amount of moisture increases the action of the manure, both as regards the crop of seeds and of straw. *Experiments in the Field*: Similar experiments were made in the field with coarse and fine grained superphosphate (23mm. and less than 1mm. diameter respectively), with Kladnoer phosphate, precipitated calcium phosphate, ground bones containing 3 per cent. of nitrogen, and with sodium nitrate. The plants employed were barley, clover, broad beans, Tartary buckwheat, Hopetown oats, lentils, rye, etc. The manure was placed 7 to 13cm. deep in the furrows, covered with earth, and the seed placed above (3 to 5cm. deep). In these experiments the action of the coarse was better than that of the fine grained superphosphate. The Kladnoer phosphate in three cases produced a heavier crop, but was less satisfactory than the superphosphate in the case of potatoes. The precipitated calcium phosphate increased the crop, but much less so than the other phosphates. The bone meal was very beneficial on account of its nitrogen. The sodium nitrate only increased the weight of the beanstalks.—S. Y.

*On the Influence of Rain, Dew, and Artificial Watering on Plants.* Prof. Jul. Wiessner. Biedermann's Central-blatt, für Agrikultur-Chemie, 12, 471. Die Weinlanke, 1883, 9, 103-104.

THE author calls attention to the fact that when a plant is moistened the transpiration of its leaves is increased, and the flow of sap becomes more rapid. A leaf which has been moistened parts with water more rapidly than one which has remained dry. The increased transpiration is beneficial or the reverse, according to the moistness of the ground. If the earth is moist the plant receives more salts, if not it withers and may even die. The foliage of a plant should therefore only be watered when the ground is sufficiently moist to supply the increased demand of the roots. The action of the dew takes place after its evaporation, and is only injurious when the ground is very dry. Rain is generally more beneficial, since the earth is moistened at the same time as the foliage.—S. Y.

*On the Injurious Action of Ammonium Thiocyanate (Sulphocyanide) on Plant Growth.* Prof. M. Märker. Biedermann's Central-blatt, für Agrikultur-Chemie, 12, 497. (Report on the Efficiency of the Research Station for Agricultural Chemistry, Halle. Zeitschrift des landw. Central-Vereins f. d. Prov. Sachsen, 1883, No. 3, 74).

THE author found that an addition of 1 per cent. of this salt to superphosphate was not injurious. Oats were uninjured when treated with even 100 kilos. per hectare. In the English gasworks the liberated ammonia is utilised by passing it over superphosphate, by which it is absorbed with formation of ammonium thiocyanate (sulphocyanide). The author thinks that the prejudice against this superphosphate should be in great part removed by his results. On the other hand, C. Schumann (Biedermann's Central-blatt 1882, Vol. 1, 332) found that meadow-land treated with about 200 kilos. of thiocyanate per hectare was very injuriously affected, while a superphosphate which contained 25 per cent. of the salt produced very bad effect on grass and potatoes. P. Wagner (Biedermann's Central-blatt, 1873, 336) noticed a similar bad effect of superphosphate containing thiocyanate in the case of barley.—S. Y.

*On the Amount of Oxalic Acid Contained in Potatoes and Malt.* Prof. M. Siewert. Biedermann's Central-blatt, für Agrikultur-Chemie, 12, 499. Die Landw. Versuchsstationen, 28, 1882, 263, 270.

THE occurrence of an incrustation of calcium oxalate in the worm condenser employed for cooling the sweet mash in a large distillery, and the observation that the oxalic acid was present in the sweet mash, induced the author to determine the quantity of oxalic acid in the mash, and in the residues. (Schlempe.) The numbers obtained were as follows: In sweet mash, 0.155gm. per litre, or

0.059 per cent. when dry. In the nearly fermented mash, 0.155 gm. and 0.4 per cent. respectively. The oxalic acid in potatoes was obtained by boiling them, converting the starch into sugar with hydrochloric acid, precipitating the lime with sodium carbonate, and finally the oxalic acid with calcium chloride. After purifying the oxalate by repeated solution and reprecipitation, the oxalic acid was estimated, and found to amount to 0.017gm., or 0.0572 per cent. As this amount appeared too small to account for the whole of the oxalate in the sweet mash, further experiments were tried with barley, malt, and germinated malt. Barley contained no oxalic acid, malt 0.0015, and germinated malt 0.064 per cent. (Vegetable glue contains 1.59 to 17.43 per cent. of oxalic acid.) Thus in breweries, where only germinated malt is made use of, the deposition of calcium oxalate is small; but as green malt is usually employed in distilleries, a portion of the oxalic acid in the malt and residues is probably derived from this source.—S. Y.

*Study of the Development of Cherries and Currants.*

Dr. Carl Anthor. Biedermann's Central-blatt, für Agrikulturchemie, 12, 499. Zeitschrift für Physiologische Chemie, vol. 7, 1883, 197-208.

FROM numerous determinations the author arrives at the following conclusions: The quantity of water and of solid residue in the case of cherries increases constantly during growth until the fruit is ripe. During the investigation this increase amounted to 398 per cent. of water and 295 per cent. of solid matter. The increase of the two is not always in the same ratio. Four weeks before maturity the increase of water is slower, before that time more rapid than that of the solid matter. The increase of ash and of phosphoric acid amounted to 204 and 195 per cent. respectively, but the ratio of these components to the water and solid residue decreases, the increase of the latter being more rapid. The percentage increase of ash and phosphoric acid in the stone amounted to 19.1 and 20 respectively. In the case of currants, both the water and solid matter increased during the investigation, which extended over six weeks, by 62 per cent. The ash during the same period increased by 50, the phosphoric acid by 47, and the sulphuric acid by 126 per cent.—S. Y.

*The Influence of Extreme Cultivation of the Soil on the Nutritiveness of Straw.* Prof. Märker. Biedermann's Central-blatt, für Agrikulturchemie 12, 500. Zeitschrift für Physiologische Chemie, vol. 7, 1883, 76-77.

THE influence of extreme cultivation appears to be prejudicial to the quality of the straw. In carefully-cultivated soil in the province of Saxony, the percentage of protein in oat-straw was found during three years to amount frequently to only 1 per cent., instead of the normal mean amount given by Wolf as 4 per cent. The injurious effect of over-cultivation may, however, be obviated by the employment of large quantities of manure. This result was brought about experimentally with Chili saltpetre and superphosphate.—S. Y.

*Experiments with Potassium Manures.* Prof. Fr. Farsky. Biedermann's Central-blatt, für Agrikulturchemie, 12, 457. Bericht der landw.-chemischen Versuchsstation in Tabor für das Jahr 1881 und 1882.

IN completion of earlier researches on the action of potassium manures (this journal Jan. 11, 1882, 210), the following experiments were undertaken—*Experiments with Pure Potassium Salts*: The chief manure employed was finely-ground bones, which was spread in the furrows beneath the seeds, and afterwards covered with earth. The potassium salt was either placed similarly under the seeds, or it was thrown three days later over the seeds, or lastly, it was placed regularly alongside the rows of plants. The results of the experiments showed that the crop was always decreased by the employment of potassium salts, the action varying with the position of the salt. The diminution was greatest when the salt was placed directly under the seeds, but less when the depth of the manure below the seeds was

greater, and much less when the salt was placed alongside the rows of plants, and therefore at some distance from the plants. The action of the chloride was less injurious than the sulphate. The after-effect of potassium salts was beneficial in the case of barley and buckwheat, the chloride being preferable to the sulphate, but the other plants could not stand the quantity of the salt employed. *Experiments with Stassfurt Manures:* (The composition of these manures is given in the above journal, Jan. 11, 1882, 490.) Similar results were obtained with these manures in the case of Tartary buckwheat and rye. Their influence was injurious, but the more dilute the solution in the earth the less marked was the action. From experiments with numerous other plants, the following conclusions were drawn: (1) The Stassfurt manures acted injuriously on barley, once also on oats, and to some extent on rye and clover, but beneficially in the other numerous cases. (2) The manure should be added in the autumn rather than the spring. (3) In the great majority of cases the chloride was more beneficial than the sulphate. The after-effect of the manures was generally beneficial in the few cases noticed. S. Y.

*On the Reduction of Nitrates in Arable Land.* Déherain and Maguene. Biedermann's Central-blatt. für Agrikulturchemie 12, 506. Annales Agronomiques 1883, vol. 9, No. 1, 6-21.

IT is well known that meadow land is much richer in nitrogen than tilled land. The researches of Déherain at Grignon showed that a soil on which maize or corn was grown became considerably poorer in nitrogen, while an unmanured soil planted with Esparto grass became gradually richer (*Central-blatt.* 12, 145). The researches of the authors on the reduction of saltpetre by ferments have been already described (*Central-blatt.* 12, 82). The difficulty of explaining the increasing richness in nitrogen of soil unexposed to the oxidising action of the atmosphere was rendered greater by Schlösing's observation that in such soils the nitrates disappeared through the nitrogen being liberated in the gaseous state. This is now better understood, and such a loss is but little to be feared, since the denitrating butyric acid ferment can only be formed in complete absence of oxygen; and in every analysis of the air contained in soil oxygen has been found to be present. In very dense soils the air might be completely removed by heavy rain, and the observation by Bonssingault of the absence of nitrates in certain soils after continued rain may perhaps be thus explained. It is possible that in tilled soil there might be spots where the air could not penetrate, or where the air in the soil was completely robbed of oxygen, and where the ferment could then be developed; but the influence of the ferment could not be very great on account of the corresponding retardation of the nitrification of the soil. The comparison by Lawes, Gilbert, and Warington of the nitrogen present in drain water as nitric acid with that contained in the crops, and the researches of the authors at Grignon on the loss of nitrogen by different methods of cultivation, allow of a more correct appreciation of the injurious effect of rapid nitrification. It appears that by retarding the formation of saltpetre, the consequent loss of nitrogen is decreased, while Schlösing's observations point to the fact that in a soil exposed to an atmosphere poor in oxygen the formation of saltpetre is slow, and there is no doubt that an excess of carbonaceous matter reduces the oxidising power of the air. Thus, one of the causes of the richness in nitrogen of unworked land is the slowness of nitrification. The great quantity of carbonaceous substances present in untilled soils affords an explanation of their increasing richness in nitrogen. Only two causes of such increase are at present known—(1) The fixation of nitrogen observed by Berthelot, and (2) the fixation of atmospheric ammonia noticed by Schlösing. Whether one or both of these causes are at work, the necessary condition is the presence of humus derived from the residues of previous plant growth, and it has been found by Bous-singault, Truchot, and other observers that meadow land is much richer in humus than ploughed land. In such soils, then, the fixation of nitrogen from the atmos-

phere is possible, while the loss of nitrogen is small, because the air penetrates with difficulty into the soil, so that nitrification is retarded. At the same time the reduction of nitrate by the butyric acid ferment cannot be great, for there must be enough oxygen present in the soil to allow of free respiration by the roots.—S. Y.

*On the Great Value of Nitrogen in Bone Dust.* Prof. Wagner Biedermann's Central-blatt. für Agrikulturchemie 12, 563. Zeitschrift für die landwirtschaftlichen Vereine des Grossherzogtums Hessen 1883, No. 12, 92.

THE bone dust of commerce contains from 1 to 4 per cent. of nitrogen, the mean being about 3.2, and 20 per cent. of phosphoric acid. The variation in the quantity of nitrogen depends on the method by which fats have been extracted. By boiling, steaming, or even drying nitrogen is lost, but if the fats are extracted by means of a solvent, such as benzene, this is not the case. Analyses of bone dust prepared in this way show a high percentage—4½ to 5—of nitrogen, and this method is therefore to be recommended.—S. Y.

*On the Manuring of Moorland.* H. J. Carsten-Hoogveen. Biedermann's Central-blatt. für Agrikulturchemie 12, 261 Landbouw-Courant, 32 Jahrg., 1882, No. 3, 10.

EXPERIMENTS were made to ascertain whether fields treated with lime in 1879 yielded in 1880 better crops than those without lime, but otherwise similarly manured with Peru guano. The lime was apparently without influence on the crop of oats. Some fresh land was manured for five consecutive years exclusively with Peru guano, 600 kilos per hectare the first year, and 450 kilos afterwards, with the result that the crop—black oats—increased gradually from 36 hectolitres the first year to 55 in the fifth. It thus appears that moorland may be converted into productive arable land solely by the use of artificial manures.—S. Y.

*Crushed Cotton Seed from Undecorticated Seeds.* Dr. Dietrich. Deutsch. Landw. Presse. Biedermann's Central-blatt. Agrik. Chem. 6, 428.

THIS product possesses a darker colour than that prepared from the decorticated seeds and is less expensive. Two samples analysed gave the following results:—

	I.	II.
Protein .....	23.56	23.06
Fat .....	6.26	7.01
Extractive matter free from nitrogen	24.94	27.12
Cellulose .....	25.73	25.53
Mineral matter .....	8.15	6.59
Water.....	11.36	10.69

E. G. C.

*On the Estimation of the Value of Different Samples of Bran.* Dr. J. Nessler (Wochenbl. Landw. Vereins in Baden, 1883, 60). Biedermann's Cent.-blatt. Agrik. Chem. 6, 428.

THE generally-received idea that fine bran is better than coarse is not correct. In purchasing bran it is much more advisable to examine whether the sample contains dark brown or black fragments (seeds of tares), or long thin pieces of chaff or straw. In both these cases the bran is less valuable.—E. G. C.

*Tobacco Manures.* Dr. J. Nessler. (Wochenbl. des Landwirtschaftl. Ver. in Baden, 19, 152-154). Biedermann's Cent.-blatt. Agrik. Chem., 9, 642.

TOBACCO requires for vigorous growth a considerable amount of potassium. This should not, however, be applied in combination with chlorine, nor should other chlorides, such as common salt, calcium chloride, etc., be made use of, as a badly-burning tobacco will be the result. Potassium nitrate and sulphate, on the other hand, increase the combustibility of tobacco manured with them. Stable manures and the like, which are generally rich in chlorides, should be used with caution,

Comparatively little phosphoric acid is required, but nitrogen must be present in considerable quantity, and in an easily assimilable form. Tobacco needs much moisture during its rapid growth, and a light moist soil agrees with it best.—E. G. C.

*On an almost entirely Barren Soil from California.* Dr. A. Voelcker. Journ. Royal Agric. Soc., 2 ser., vol. 19, 236-237.

THIS soil possessed the following composition:—

Soluble organic matter	with 0.09 nitrogen	0.75
Insoluble organic matter		2.44
Oxide of iron		1.48
Alumina		1.54
Carbonate of lime		2.58
Magnesia		1.50
Potassium nitrate		0.17
Sodium chloride		0.04
Sodium		0.58
Potassium		0.81
Sulphuric acid		trace
Phosphoric acid		0.19
Insoluble siliceous matter		81.92
		100.00

The explanation of the unproductiveness of this soil is to be found in the circumstance that its reaction was strongly alkaline. It yielded to cold water  $\frac{1}{2}$  per cent. of mineral constituents, consisting of carbonates of soda and potash, sodium chloride, and sodium nitrate. In order to convert such a soil into fruitful land, the author knows of no other method than to inundate from time to time with water, and so wash out the excess of alkaline salts.—E. G. C.

*A Further Proof that the Albumen of Living Protoplasm possesses a Different Constitution from that of Dead Protoplasm.* (O. Loew. Arch. für Physiol. 1883, vols. 7 and 8, 348-362.) Biedermann's Cent.-blatt. Agrik. Chem. 9, 645.

THE blackening which living plant-cells exhibit under the influence of a highly dilute ammoniacal silver solution is, according to the author's previous researches, to be attributed to the peculiar chemical character of living albumen. No doubt the relatively large quantity of metallic silver which the living cells are able to separate shows that the principal substance of the cell-contents, the albumen, is concerned in the reaction. The author first of all isolated and analysed the albumen of the alga, *spirogyra dubia*, in the fresh condition, and then, from the same alga, after treatment with silver solution, he isolated a silver compound and also analysed this. On a comparison of the albumen of the fresh alga with that in the silver compound it was found that the latter was much richer in oxygen than the former. From the alga previously treated with alcohol a similar silver compound could not be obtained. In the existence of this compound, the author perceives a proof that only living albumen takes part in the blackening of the cells.—E. G. C.

*Analyses of Various Cattle Foods.* Dr. A. Voelcker. Journ. Royal Agric. Soc., 2 ser., vol. 19, 237-242.

GREEN rye, preserved in silos, had the following composition:—

Moisture	72.50
Lactic acid	0.80
Nitrogenous substances (with 0.31 N)	1.99
Extractive matter	12.86
Cellulose	9.72
Ash	2.13
	100.00

This fodder was willingly taken by sheep and cattle; cows fed on it gave abundance of milk.

#### LOCUST BEANS.

	Pods and Seeds.	Seeds.
Moisture	14.73	14.11
Fat	0.62	2.03
Albuminoids	5.62	16.94
Sugar	10.01	—
Cellulose	5.27	8.81
Extractive matter	30.99	51.50
Ash	2.76	3.61
	100.00	100.00

The pods contain a large quantity of sugar, and therefore less nitrogenous constituents, while the seeds contain scarcely any sugar. The pods, although a useful fodder, should not be given in too large amounts, because of their exceedingly sweet taste and the small proportion of nitrogenous matter present. The seeds ground to powder furnish an easily digestible and nourishing fodder. Dari-seeds (a kind of sorghum) and millet contained the following constituents:—

	Dari-seeds.	Millet Crushed.	Millet Uncrushed.
Moisture	12.55	12.85	13.19
Fat	2.93	3.91	3.83
Nitrogenous substances	10.31	11.25	9.56
Extractive matter	70.43	69.25	57.06
Cellulose	1.63	7.73	12.51
Ash	2.15	4.01	3.85
	100.00	100.00	100.00

Both foods are comparatively poor in albuminoids, and it is therefore advisable to mix them with fodder richer in nitrogen, such as crushed beans, etc. Russian linseed cake of great purity contained:—

Moisture	11.13
Fat	10.73
Albuminoids	36.62
Extractive matter	28.22
Cellulose	7.91
Ash	5.39
	100.00

E. G. C.

*Experiments on the Digestibility of Wheaten Bran and its Alteration by Various Methods of Preparation and Administration, and on the Digestibility of Dry and Moistened Meadow Hay.* G. Kühn, F. Gerver, M. Schmöger, A. Thomas, O. Kern, R. Struve, and O. Neubert. Die landw. Versuchs. Stationen, Jahrg. 1883, 29, 1-214. Biedermann's Central-blatt. für Agrikulturchemie 12, 459.

THE object of the experiments was to ascertain whether the supposed increased wholesomeness of bran and other fodders when soaked in hot water, boiled, or administered in the form of broth, either alone or mixed with other fodders, was due to their greater digestibility when so treated. That no increase of digestibility in the case of bran is produced by boiling or disintegration was shown by previous experiments. As the bran could only be given in conjunction with another fodder, meadow hay, the digestibility of the latter when dry and moistened was first ascertained, and then the digestibility of the mixture under different conditions. From their experiments the authors draw the following conclusions: (1) The simple moistening of the hay immediately before its administration, either with water or with bran prepared as broth, has no sensible influence on the digestibility of the fodder, so long as the quantity of water employed is less than the total amount required by the animals. (2) Even when the amount of cold water employed is greater, it has no influence on the digestibility of the mixed fodder or on that of the bran. (3) The softening of the bran with cold water by standing for twenty-four hours has no influence on the digestibility of the mixed fodder or of the bran when the water taken by the animal in the ordinary way is not reduced by more than 50 per cent.; but when the quantity of water thus taken is reduced to below about 25 per cent. of the normal amount, the amount of raw protein digested is reduced both in the case of the mixed fodder and of the bran. (4) By soaking the bran with boiling water and allowing it to stand for twenty-four hours, the digestibility of the mixed fodder as regards raw protein is reduced, and the higher the initial temperature and the longer the application of heat the greater is this reduction. (5) The separate administration of the bran as a drink (in conjunction with dry fodder), and the administration of similarly-prepared bran mixed with the hay, give sensibly identical results. (6) The reduction of the digestibility of the raw protein when the bran is treated with boiling water is due to the action of the heat on the albumen of the bran, and it is the protein in the bran and not in the hay that is affected. Although only two kinds of fodder, meadow

hay, and wheat bran were employed in these experiments, the authors consider it probable that their conclusions may be extended to other fodders. The methods of preparation described, as well as—in other cases—steaming, disintegration, fermentation, or simple heating, have no beneficial effect on the digestibility of the fodder, but rather reduce that of the protein, and they are therefore not to be recommended, except in special cases, when the fodder is rendered more palatable by such treatment.—S. Y.

*The Influence of Superphosphate on the Quality of Crops.* Prof. Fr. Farsky. Biedermann's Central-blatt. für Agrikulturchemie 12, 511. Bericht der landw. chemischen Versuchsstation in Tabor in den Jahren, 1881 bis 1882.

IN some experiments on the action of Chili saltpetre and superphosphate as manures the author observed considerable differences in the crops of buckwheat and in the lateness or earliness of maturity. This is shown by the subjoined table:—

Description of Manure.			Moisture of Soil.	No. of days before Maturity.	Weight of seeds in grms.	
Chili Saltpetre.	Coarse Superphosphate.	Fine Superphosphate.			25c.c.	100 grains.
Not manured	—	—	Regulated	110	11'8254	0'9125
Ditto	—	—	Larger quantity	115	11'7995	0'9412
Saltpetre	—	—	Regulated	120	11'8294	1'0271
Ditto	—	—	More	120	11'8213	1'0272
—	Low percentage	—	Regulated	100	11'9836	1'1178
—	Ditto	—	More	106	11'9908	1'1479
—	—	Low percentage	Regulated	100	11'9075	1'1459
—	—	Ditto	More	108	11'8940	1'1463
Saltpetre	Low percentage	—	Regulated	110	11'8786	1'1572
Ditto	Ditto	—	More	115	11'8742	1'1580
Ditto	—	Low percentage	Regulated	110	11'8706	1'1568
Ditto	—	Ditto	More	115	11'8702	1'1556
Ditto	High percentage	—	Regulated	108	11'8877	1'2071
Ditto	Ditto	—	More	110	11'8691	1'2075
Ditto	—	High percentage	Regulated	108	11'8599	1'2064
Ditto	—	—	More	110	11'8500	1'2062

The harvest of buckwheat was gathered as soon as any seeds fell when the plants were gently shaken, whether they were still growing or not. The author draws the following conclusions: (1) The superphosphate acts as a stimulant and hastens the time of maturity. (2) The superphosphate increases the absolute and relative weight of the seeds, so that the present demands of the corn trade may be satisfied by its employment. (3) The Chili saltpetre does not increase the weight of the seeds, but rather delays the harvest.—S. Y.

*The Slow Weathering of Crude Bone Dust.* Prof. J. König. Biedermann's Central-blatt. für Agrikulturchemie 12, 562. Allgemeine Zeitung für deutsche Land-und Forstwirte, 12 Jahrg., 1882, 90, 551.

A FIELD treated in the spring with stable manure and steamed bone dust contained no remains of bones even in the same year, while in other fields, manured from two to four years before with crude bone dust and stable manure, splinters of bone as large or even larger than peas were found. From analyses of these splinters, it would appear that the splinters in crude bone dust may lie in the ground four years before they are completely weathered.—S. Y.

*Improvements in the Manufacture of Artificial Fertilisers.* T. W. B. Munford, London. Eng. Pat. 3343, July 5, 1883.

"I TAKE finely-ground commercial phosphorite, containing either a high or low percentage of phosphoric acid, and after dissolving the same in sulphuric acid of from 117° to 120° Tw., I agitate the mixture in a

vessel with either hot or cold water, passing the thin muddy product through an iron and lead filter press, or centrifugal or other suitable machine. The filtered solution contains the phosphoric acid in a soluble state, and the solid residue consists of a small percentage of soluble and insoluble phosphoric acid, sulphate of lime, and silica, and is a valuable fertiliser for certain crops. The solution of soluble phosphoric acid I run into shallow leaden pans, which may be situated on the top of pyrites or other kilns, or places where waste heat is available; and I evaporate the solution at a low temperature, until the liquid becomes highly concentrated and of a syrupy consistency. To this concentrated liquid I add, by means of an ordinary manure-mixer, or in other convenient way, a quantity of finely-ground ordinary commercial phosphorite. I have found the proportions of 1 part by weight of phosphorite to 2 parts by weight of the liquid to give good results. To these combined materials I add sulphuric acid of, preferably, 150° Tw. I have found that 1 part by weight of sulphuric acid to 6 parts by weight of the materials gives good results. The resulting product is a mixture resembling

ordinary superphosphate of lime, which in a few days becomes dry and hard, and capable of being ground or disintegrated into a very finely-divided and dry powder, and which, under ordinary atmospheric influence, does not lose its condition, and retains the phosphoric acid in a soluble state."

## XV.—SUGAR, GUMS, STARCHES, Etc.

*On the Formation of Mannite from Dextrose and Levulose.* F. W. Daferri. Berl. Ber. 17, 227.

C. SCHEIELER has recently concluded from various observations that the formation of mannite from dextrose and levulose, by the action of sodium amalgam, is due to a secondary process (Berl. Ber. 16, 3010). The author has arrived at the same conclusion, at any rate as regards dextrose, from a study of the oxidation products of mannite. The products of oxidation of mannite vary according to the nature of the oxidising agent, the time of action, and the temperature: they are carbon dioxide, water, formic acid, mannitic acid, saccharic acid, inactive tartaric acid, and probably glycollic acid. Besides these a product is formed, when the oxidation is carefully conducted, which is identical with the mixture of a fermentable sugar and a substance resembling mannitan, first observed by Gorup-Besanez (Ann. Chem. Pharm. 118, 257). Further investigation of these bodies has shown (1) that the so-called mannitose belongs to the group of glucoses, and (2) that the mannitose does not differ from grape sugar, as Gorup-Besanez states, only by its optical inactivity but also in its behaviour with

hydrochloric acid, sulphuric acid, Fehling's and Knapp's solutions. The similarity in the behaviour of mannitol and levulose is very striking, and the author would pronounce them to be identical if the former could be obtained in a clearly optically active state. The properties of the second body are not characteristic; it has an insipid taste, does not reduce Fehling's solution, is not fermentable, and is probably optically inactive, and thus resembles the little-known compounds mannitan and dextran. The author has never observed the formation of dextrose. When the mixture is treated with sodium amalgam mannite is re-formed, whence the author concludes that it cannot be in consequence of unsuitable conditions of oxidation that dextrose is not formed from the same mannite which is formed by the reduction of dextrose, when, under the same conditions, the easily decomposed mannitol is formed from mannite; or, in other words, that it is not from dextrose, but from a secondary product, possibly the second of the two substances mentioned above, to which Gorup-Besanez gives the formula—

that the mannite is formed by reduction. By renewed oxidation of the two substances the capability of reduction is diminished, whence they cannot be regarded as intermediate products between mannite and dextrose. The author has only recently been able to separate the mannitol from the other substance, and he is therefore as yet unable to say whether it is physically isomeric or identical with levulose, or whether it is also a secondary product.—S. Y.

*Record of a Year's Working of a Sugar Refinery.* G. Stale. Geitschrift des deutschen Vereins für Rübenzucker 1883, 797, and Dingl. Polyt. Journ. 251, 127, 1884.

A MINUTE and detailed account is here given of a year's working of a refinery which dealt principally with crude sugar from the district of Magdeburg and Brunswick. During that period 5777.3 tons of raw sugar passed into the factory, the average composition of this being—

		In 100 parts Dry Substance.	To 100 parts of Sugar.
Sugar .....	96.39	97.96	—
Water .....	1.60	—	—
Non-saccharine substances .....	2.01	2.04	2.00
Ash .....	0.99	1.01	1.03

The finished products were of six different qualities: the absolute yield of each, the amount obtained from 100 parts of crude sugar worked up, and the composition of each quality, are here given—

Name of Quality.	Absolute Weight Obtained	Amount of Pro- duct from 100 parts of Crude Sugar.	Composition per cent.			
			Sugar.	Non- Sugar.	Ash.	Water
	Tons.					
Candy, white, & half white .....	975.579	16.89	100	—	—	—
Candy, yellow and dark yellow .....	87.981	1.52	99.8	—	—	—
Lump sugar in loaves of 12½ kg. ....	1421.615	24.66	99.4 to 99.8	—	0.3 to 0.1	—
Lump sugar crushed .....	1391.965	27.55	99.4 to 99.8	—	0.3 to 0.1	—
Lump sugar in tablets .....	1021.250	17.68	99.4 to 99.8	—	0.3 to 0.1	—
Brown sugar ..	118.667	2.06	91.57	5.71	2.36	2.72
Osmose-water concentrated ..	81.000	1.40	12.13	11.39	18.81	16.18
Syrup .....	316.230	5.47	56.61	26.63	9.79	16.74
Total .....	5617.307	97.23	—	—	—	—

It is thus apparent that a total loss of 159.993 tons took place—that is to say, 2.77 per cent. calculated upon the crude sugar. Now, from the known percentage composition of the raw sugar treated, it was calculated that 5568.7 tons of pure sugar passed through the works. Of this, 5424.3 tons were obtained as pure sugar in the finished products. The loss of pure sugar was therefore 144.4 tons—that is to say, 2.59 in 100 parts of pure sugar, or 2.50 in 100 parts of raw sugar. It was found that for every 100 parts of loss 19.33 took place in the animal charcoal, 25.92 in the sweet waste water, and 54.15 which could not be referred to any particular stage. Of the mineral matters a loss of 8.862 tons took place, this item passing out of the factory in the processes of filtration. The following summary will give a clear idea of the degree of efficiency attained to in these works: 100 parts of pure sugar in the crude material yielded 93.366 of refined sugar, 0.638 sugar in the osmose water, 3.346 sugar in the syrup, and 2.650 of loss. If the sugar in the osmose water and that in the syrup be brought under the one heading of syrup, that item becomes 3.984. If, however, the osmose water be regarded as loss, then the yield for every 100 parts becomes—93.366 refined sugar, 3.346 syrup, and 3.288 loss. As regards the consumption of fuel, 100 parts of crude sugar required 144.7 of Westphalian anthracite, with 1.9 per cent. of water and 10.8 per cent. of ash. This extraordinary consumption is due to the poor calorific value of this fuel, and is to be partially ascribed, moreover, to the plant and machinery not being of the most advantageous form.

W. D. B.

*Improvements in Extracting Sugar from Molasses, and in Apparatus connected therewith.* J. H. Johnson, London. Communicated by J. E. Boivin and M. M. D. Loiseau, Paris. Eng. Pat. 3093, June 21, 1883.

THIS invention "is concerned with the extraction of sugar from molasses." A "molasso-calcareous mixture is prepared with suitable proportions of lime and diluted molasses," and "a sacrate of hydrocarbonate of lime is formed with the said mixture" by treatment of it by CO<sub>2</sub>. The "sacrate of hydrocarbonate of lime" is then washed, and then decomposed by CO<sub>2</sub>, and finally "the mixture of carbonate of lime and saccharine liquid resulting from this operation is subjected to the usual treatment in order to obtain sugar therefrom."

*Improved Processes for Defecating or Clarifying Saccharine Liquors, which Invention also comprises a Compound for Use in such Processes.* H. H. Lake, London. Communicated by H. A. Hughes, Camden, New Jersey. Eng. Pat. 3397, July 9, 1883.

To separate from cane-juice or other similar saccharine liquor "all or the greater portion of the matters contained therein other than sugar and water," the author of this invention adds to such juice or liquor bisulphite of lime before subjecting it to the ordinary process of defecation. He then treats the defecated juice by a weak solution of sulphuric acid, and then injects steam into it to drive off all SO<sub>2</sub>.

## XVI.—BREWING, WINES, SPIRITS, Etc.

*The Pasteurisation of Beer.* M. Schwarz. Biedermann's Central-blatt. für Agrikulturchemie 12, 560. Allgemeine Brauer- u. Hopfenzeitung, Jahrg. 23, 1883, 23, 227-228.

A STATEMENT by Behrend that yeast is only partially killed by warming, and that it recovers after a time, led the author to make some experiments to ascertain the truth of this assertion. Solutions containing yeast were exposed to temperatures ranging from 10° to 55° C. and the percentage of dead cells counted. The number rose from 16.6 per cent. at 40°, to 100 per cent. at 55°, and the cells after being heated to the latter temperature, when placed in fresh malt extract and kept at a temperature of 5° to 7°, showed no signs of life even after 40 hours. In practice the bottled beer is placed in cold water, which

is then heated by the introduction of steam, or the bottles are placed in a steam bath. The great point is that every bottle shall be raised to the required temperature, but an error frequently occurs because the temperature of the water is observed and not that of the beer; while the want of uniformity in the quality and thickness of the bottles, and the unequal temperature of the water when heated by steam, also lead to mistakes. Experiments made by the author showed that the temperature of the beer in such cases is from 2° to 3° lower than that of the water, though the whole of the beer in each bottle attains an almost uniform temperature. It is thus seen that the water should be heated for a considerable time to 58°. Beer which has been imperfectly heated, as well as beer which contains healthy yeast-cells, remains clear in a cold place, but at the ordinary temperature they both become turbid, and are found to contain living yeast-cells, bacteria, moulds, albuminates, and some resinous matter from the hops. The author finds that the turbidity of beer which has been properly heated is due to a separation of gluten, and that such turbid beer, when heated to 50°, becomes clear again and will remain so for a considerable time. —

S. Y.

*Improvements in the Manufacture of Maltose and its Applications.* J. Imray, London. Communicated by L. Cuisinier, Paris. Eng. Pat. 3437, July 12, 1883.

"ACCORDING to this invention, starch has added to it water and from 5 to 10 per cent. of what may be termed 'infusion'—that is to say, the liquid extracted from germinating grain. The whole is thoroughly mixed in a vessel heated slowly by a steam jacket to about 80° C. during about one hour. The liquid mixture is then poured into a close vessel provided with an agitator, and heated for about half an hour till the pressure is about an atmosphere and a half. The liquid is then cooled by surfaces kept cool by circulation of water, to about 48° C., and then has added to it 5 to 10 per cent. of infusion, according as saccharification is desired to take place less or more rapidly. When saccharification has continued about an hour, the juice is filtered by a filter press through filter paper supported on fabric, and the liquid product may then be kept for several days without alteration at a temperature of 48° C. The liquid is concentrated in a vacuum pan to about 28°, and filtered through animal charcoal in filters heated and closed in the usual way." Methods are described of treating "potatoes, and roots of like kind," and also "cereals, such as maize," directly.

*Improvements in the Means for Promoting and Improving the Fermentation of Wine, Beer, and other Beverages.* F. Wirth, Frankfort-on-the-Main, Germany. Communicated by A. Reihlen, Stuttgart. Eng. Pat. 3321, July 4, 1883.

"This invention relates to the preparation and use of fibres for promoting fermentation in wine, beer, and other beverages, and is based upon the fact that not only do woody fibres and vegetable cellular substances in their minutest form become impregnated with fungoid growths when they are in contact with substances in a state of fermentation, but they may also be impregnated with the same growths deriving their germs direct from the air under favourable conditions. The fibres impregnated with the said fungoid growths may be used as ferment instead of yeast, but without the disadvantages attending the use of the same." One of these advantages is stated to be that yeast always contains "a varied quantity of fungoid growths, some of which are diseased." To obtain the prepared fibres which he proposes to use instead of yeast, the inventor pours "pasteurised beer over clean woody fibres or cellulose. At a suitable temperature for fermentation, the fungoid growths which develop in the fermentation of beer, deriving further germs from their contact with the air, are thus multiplied." "For the purpose of fermenting beer wort, it is necessary to select suitable vegetable substance as feeding grounds for the fungoid growths, and then to fix these

fungoid growths upon the material selected." The inventor's specification describes his methods of procedure, and the various advantages which he believes to attend the use of his "prepared fibres" instead of yeast, in considerable detail.

*Improvements in Treating Alcoholic Liquors with Electricity to Purify and Impart to them the Character of Age.* Communicated by A. C. Tichenor, Alamada, California, U.S.A., to W. E. Gedge, London. Eng. Pat. 3877, Aug. 9, 1883.

THIS invention consists in "removing fusel oils or other impurities from alcoholic liquors" by "passing through them an electric current by means of wires and electrodes, one of which" electrodes, namely, the negative one, "is provided with a removable envelope or casing," which may be removed when it has become "thickly coated with a slimy or viscid substance," and another instantly substituted for it. The said removable envelope may be of "Canton flannel, woollen cloth, or other fibrous textile material." When the liquor treated is whisky, it should be treated "in tubs or vats of about one barrel capacity," by the current from a dynamo machine "having a strength or power equal to a Daniell battery of 40 cells." A current of about one-third of this strength should be used for wines. In treating wines, the electrodes used should be metal plates. In treating whisky, they should be carbon plates.

*Improvements in Preserving Milk, Fruit, or other Organic Substances.* W. H. Thew, Waterloo, Lancashire. Eng. Pat. 3058, June 20, 1883.

THIS invention consists: "First, in subjecting the substance to be preserved, and which is contained in a tin or other suitable germ-proof vessel, to a temperature which is sufficient to kill the fully-developed organisms, and which varies in different cases between 150° and 200° Fahr., and keeping it at this temperature for a period of between one and two hours. Secondly, in allowing the heated vessel to cool to the mean temperature of dwelling-rooms. Thirdly, in repeating these alternate processes of heating and cooling at intervals of between twelve to twenty-four hours, for a number of times, depending upon the substance to be preserved, but which usually is not less than five times. The theory of the process is the following: The more fully-developed organisms which are the immediate cause of the fermentations and decompositions to be prevented are killed by the repeated and lengthened exposure to 150° or to 180° Fahr. In the times which elapse whilst the substance is cooling from this temperature to that of the air, or which elapse during the heating up of the substance from the ordinary temperature to 150° or to 180° Fahr., the germs yet unacted upon are exposed to temperatures most conducive to their development, and developing become amenable to the destructive action of temperatures of 150° and 180° Fahr."

## XVIII.—SANITARY CHEMISTRY, DISINFECTANTS.

*Improvements in the Purification of Sewage Waters and the like, and the Recovery of Valuable Products therefrom.* Dr. J. Boek, Puschkau, Germany. Eng. Pat. 3252, June 30, 1883.

By this invention there is first added to sewage, per cubic metre thereof, "250grms. of wood pulp, or paper fibre, 140grms. of chloride of iron, 100grms. of concentrated solution of chloride of magnesium, and 1,500grms. of lime in the form of milk of lime." The mixture is allowed to settle, and then the supernatant liquor is decanted off. The precipitate, which is said to "contain all the phosphoric acid as well as all the nitrogen" of the sewage from which it has been precipitated, is pressed and dried for use as manure. The filtrate is first "treated by an oxidising agent," preferably "manganate of an alkali, in the proportion of about 100grms. per cubic metre," and then by a quantity of sulphurous acid a little greater than the quantity necessary to form

normal sulphite with all the lime in it. There is thus formed "a very small proportion of bisulphite of lime, which to a very high degree possesses the property of keeping the water entirely unaltered for a long time."<sup>4</sup>

### XIX.—PAPER, PASTEBOARD, Etc.

*An Improved Process of Making a kind of Fibrous Lignous Cellulose suitable for Paper-making and for other Purposes to which Cellulose is applicable.* A. M. Clark, London. Communicated by R. Blitz, Paris. Eng. Pat. 3240, June 29, 1883.

This invention consists in digesting "any kind of soft wood or other fibrous vegetable material" for from 4 to 8 hours, under a pressure of 3 to 4 atmospheres, with water to which has been added, per 127 cubic feet of wood to be treated, "13 pounds of hydrosulphite of soda, 6½ pounds of caustic soda, and 15 grains of vanadate of ammonia, dissolved in 60 grains of hydrochloric acid."

*Improvements in the Preparation and Manufacture of a Compound from Vegetable Materials suitable for Electro Non-conductors and Insulators; applicable also to other useful purposes.* E. C. T. Blake, Brixton. Eng. Pat. 3127, June 23, 1883.

By this invention, "one-third by weight of ground waste cork, and two-thirds of dry wood pulp or waste fibrous materials (advantageously waste cocoa-nut fibre)," are to be "mixed with the colloid of fibrin of blood, or instead thereof with paste or other material (advantageously made of rye or rice flour)," and the mixture, "in a thick pulpy state," is to be "put into moulds and kept under a continuously increasing pressure until all the watery parts are removed." The "boards, blocks, or other unworked forms" so obtained are then to be thoroughly dried, and thereafter well soaked "in boiling linseed oil or other waterproofing material," and then baked at 212° F. They are then to be again soaked in linseed oil or the like, and then to be again baked. They are said to be then "perfectly waterproof, and diluted acid proof," and "in appearance similar to ebonite."

*Improvements in Boilers or Vessels Employed in the Treatment of Fibrous Materials for the Manufacture of Paper Pulp, or for other purposes.* J. T. McDougall, Manchester. Eng. Pat. 3257, June 30, 1883.

In the lead-lined boilers which have hitherto been employed for digesting wood and other fibrous materials in acid solutions "a considerable difficulty has hitherto been experienced in keeping the lead in its relative position with the casing when the boiler or vessel is submitted to high temperatures. The repeated action of heat upon lead causes it to continually increase in area, and thus gradually accumulate into ridges or creases, which soon break, and necessitate the relining of the boilers or vessels. Most metals, such as steel and iron, expand when heated, and return to their original volume on cooling. Lead does not possess this power of returning to its original area after expansion." By the present invention it is proposed to secure the lining of lead-lined boilers "to the casing of the boiler, in such manner that the creeping or sliding effect of the lead is localised into sufficiently small portions to make the lead lining much more durable than" hitherto. This is to be accomplished "by providing a sufficient number of suitable holes through the casing, and corresponding holes in the lead lining, and passing through both these holes bolts or fastenings, having a head or the like on the inside, and being provided on the outside with one or more nuts or other means for tightening or holding the lead lining and the outer casing firmly together, so as to hold the lead lining in position to the casing. These bolts or fastenings should by preference be fixed at distances not very far apart, say about from 9in. to 24in. in every direction, according to the thickness of the lead lining, and the temperature to which the vessel is required to be subjected."

### XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

*Action of Sodium upon Camphor.* J. Kachler and F. O. Spitzer, Monatsh. f. Chem. 4, 494.

THE products of this reaction are, according to Baubigny, the sodium compounds of camphor and of borneol. The authors have investigated the reaction under the condition of exclusion of oxygen, viz., by employing a low-boiling petroleum ether as the solvent for the camphor, and allowing the reaction to proceed in an atmosphere of hydrogen. The sodium compounds were then dissolved in water, the solution filtered from a small residue of camphor, and decomposed by hydrochloric acid. The resulting precipitate was resolved, by fractional crystallisation into (a) white shining plates, melting point 140°, insoluble in water, freely soluble in alcohol and in ether, and having the composition  $C_{20}H_{30}O_{2.5}$ , and (b) camphoric anhydride,  $C_{10}H_{14}O_4$ . This paper is a preliminary notice of an extended investigation of the subject.—C. F. C.

*Papaverine.* G. Goldschmidt, Monatsh. f. Chem. 4, 704.

PAPAYERINE yields, on fusion with potash, methylamine and dimethylhomopyrrocathecol, together with protocatechuic acid, the latter being the chief product. It does not yield an acetyl derivative. Heated with hydrochloric acid at 130° it yields methyl chloride. The author is engaged in prosecuting the investigation, of which this is a preliminary notice.—C. F. C.

*Caffeine and Theobromine.* E. Schmidt, Dingl. Polyt. Journ. 251, 144, 1884. From Archiv. der Pharmacie, 221, 656, 1883.

ALTHOUGH caffeine is to be regarded as methyl-theobromine, or tri-methyl-xanthine, the author has not succeeded in converting it into theobromine by abstracting a  $CH_3$  group by the action of hydrochloric acid. He considers that hydrochloric acid induces the decomposition according to the equation—

For the preparation of theobromine, the author mixes cocoa of commerce with one-half of its weight of fresh slaked lime, and extracts the mixture with boiling alcohol of 80 per cent. On cooling the alcoholic extract, pure theobromine crystallises out. The base so obtained is a white crystalline powder in the anhydrous condition. It sublimes with little alteration at 290° C. and its analysis leads to the formula  $C_7H_8N_4O_2$ . To convert theobromine into caffeine, equivalent quantities of theobromine, methyl iodide, and potassium hydrate in alcoholic solution are heated for some time at 100° C. The theoretical amount of caffeine is not obtained, as a portion of the theobromine appears to suffer decomposition, but in its chemical and physical properties the caffeine thus produced appears identical with that occurring naturally, and with the product of the action of methyl iodide upon silver theobromine. The author has observed the presence of caffeine in the last mother-liquors, from which theobromine has been separated in its preparation, as above described, from cocoa.

W. D. B.

### XXI.—EXPLOSIVES, MATCHES, Etc.

*Improvements in Explosives.* Dingl. Polyt. Journ. 251, 118, 1884.

SALANVILLE and Lalignant (Ger. Pat. 19839, April 12, 1881) propose to employ a mixture of potassium or sodium hydrogen sulphate, potassium or sodium nitrate and glycerin, which is said to produce nitro-glycerin when ignited by means of a priming composed of potassium chlorate and carbonaceous matter. The explosion is stated to be direct. J. Gemperle (Ger. Pat. 23933, December 10, 1882) prepares "amidogene" as under: 73 parts of potassium nitrate and 1 part of magnesium

sulphate are dissolved in one-third of their weight of boiling water. On solution being complete, 8 parts of ground wood charcoal, 8 parts of bran, and 10 parts of sulphur are added, and the whole allowed to digest for 2 hours at 140° C. The mixture is dried for 5 hours at 50° C. and compressed into cartridges under a pressure of 5,000 atmospheres—a pressure which is ten times as great as could possibly be required, and which is likely

to give rise to accidents. It is claimed that the operation of compressing this compound is absolutely devoid of danger. Such a statement is to be received with caution, for although the elasticity of the bulky carbonaceous matter possibly renders that operation less dangerous than is the case with ordinary black powder, yet experience shows that no explosive can be very power-

fully compressed without risk. In order to decrease the length, and thereby increase the durability, of the needle required for the perforation of prismatic powder, Schwartzkopf (Ger. Pat. 16712, April 17, 1881) adopts the arrangement here illustrated. In the centre of the bearing guide *a* of the inferior plunger *b* a rectangular cavity is cut, its sides being parallel to the sides of the guide. At its lower end the plunger *b* is actuated. Into

*b* the pin *h* is screwed, and *h* presses forward the cylinder *g*, to which the needle is attached. The cylinder *g* is retained by the cap *f*, which is kept in position by the tubes *d* screwed into the upper side of the plunger *b*. In the operation of compressing powder cake, Glaser (Ger. Pat. 16763, July 17, 1881) advocates the employment of ebonite press plates, which, by reason of their elasticity, oppose continuous resistance to the pressure without being injuriously affected as to the regularity and smoothness of their surface. The plan devised by Gruson and Hellhoff (Ger. Pat. 19430, March 3, 1882) for the application of liquid explosives is an attempt to solve a most difficult problem, one which, so far as nitroglycerin is concerned, yet remains unsolved. Tubes of tin plate, with soldered seam, are cut to the right length and closed at the bottom either by forcing the end through a stellate die, as shown in Fig. 3, by folding the

end in plaits by means of a tightened cord, as in Fig. 4, or by twisting the end with a screwing motion, as in Fig. 5, and in each case soldering up the joints. In the neck an iron cap, screwed internally at its mouth, is soldered. This serves to contain the detonator, whose shell is made of tin, and is kept in position by being pressed into the female conical screw of the iron cap by means of the male screwed tap shown in Fig. 6. The detonating agent is placed in this tin cap, surrounded with the safety fuse, which is fixed by nipping the sides of the tin tube upon it. The whole detonator is then rendered impervious to water by means of cement. The patenting of a method for preparing quick-matches from straw haulms would rightly be considered a retrogressive step in these days of the *Bickford safety* and other fuses, were it not that in some localities the miners adhere most tenaciously to the old form. Pietzka (Ger. Pat. 16866, May 14, 1881) fixes the haulms gathered together in a bundle in a frame, and brings the ends into the conical mouthpiece of the same funnel through which the fine-grained powder is shaken into the haulms. In the *Mittheilungen über Gegenstände des Artillerie- und Genie- Wesens*, 1883, 85, Hess contributes his results of a series of experiments in connection with the exudation of nitro-glycerin from dynamite, consequent on the repeated freezing and thawing of the cartridge. A cartridge of kieselguhr dynamite, containing 71.63 per cent. of nitro-glycerin, was imbedded in kieselguhr, and frozen and thawed alternately three times. The surface was then found to contain only 67.52 per cent. of nitro-glycerin. The average amount of nitro-glycerin in the whole cartridge

had sunk to 71.42 per cent. The cartridge was then wrapt in paper saturated with paraffin, and again frozen and thawed three times. The percentage of nitro-glycerin at the surface was found to be 70.99. It is evident that in the first instance the loss was due to an absorption of the exuded nitro-glycerin by the surrounding kieselguhr. To test the stability and complete purification of explosive substances principally of the nitro-compound class, Hess proposes to expose the same in an air-bath to a temperature of 70° C., and compare the indications of a thermometer, whose bulb is plunged into the explosive, with those of one in the air-bath, it being assumed that the cause of an excess of temperature is incipient decomposition of the explosive. The apparatus here figured (Fig. 7) consists of the bath

W, provided with the thermo-regulator R and thermometer T. The explosive under examination is contained in the vessels P P P. These have double sides, the intervening space being filled with kieselguhr. Thermometers *t* pass through the top of the bath and rest in the explosive, of which samples of about 100grms. will suffice to afford reliable results. To obviate any possible danger during the testing of doubtful samples, the arrangement of the middle tube may be adopted. This is perforated near the top, closed with a cover, and suspended by a flange. By means of the cord S, which passes over a pulley, the explosive may be easily removed from the bath and plunged into water. The method appears simple, and possesses the advantage over the tests hitherto in use that a larger quantity of the explosive can be taken. As, however, dynamite, for instance, usually occurs in commerce in cartridges of less than 100grms. weight, it would be very interesting to observe whether the quantity of material taken for this test has any influence upon the results. For waterproofing the Bickford safety fuse, tallow may be employed, but Hess recommends a mixture of 6 parts of wax, 1 part of asphalt, and 1 part of resin, melted at 160° C. It is, however, useless to attempt to waterproof a Bickford fuse when the spark is sufficient to rupture the casing, for that would at once permit the ingress of water. With the aid of Sébert's Velocimeter, Sébert and Hugoniot confirm the fact, often hitherto observed in practice, that the velocity of explosion of a charge is directly proportional to the resistant pressure. The dynamite employed in the criminal attempts upon the Government and Times offices, on March 15th, 1883, was shown by Dupré to possess the following composition: Nitro-glycerin, 29.8 parts; sawdust, partially carbonised, 63.8 parts; moisture, 6.4 parts. The sawdust was coarse, and of a dark brown colour. The specific gravity of the dynamite was only 0.33. This dynamite was not very sensitive to percussion, and when detonated in a lead cylinder produced a cavity of 17 volumes as compared with that of 45 produced by Nobel's

No. 1 dynamite. The accidental explosion of five incorporating mills in the works at Basinghall, owing to lightning, demonstrates the necessity not only of providing danger buildings with sufficient lightning conductors, but likewise of keeping their earth terminals in thorough working order. The avoidance moreover of sharp bends in the conductor is very desirable. In the *Zeitschrift des österreichischen Ingenieur- und Architektenvereins*, 1882, page 121, Hajnat, Santay, and others publish interesting results of the methods employed in quarrying limestone for the construction of the harbour of Fiume. The three principal quarries worked were those of Martinschizza, Zurkovo, and Prelucea. In the two former the limestone was full of interstices, in the latter only was it compact. By reason of its price and convenient form, the explosive known as "diorexine" was exclusively employed. Diorexine is composed of 42.78 parts of potassium nitrate, 23.16 parts of sodium nitrate, 13.40 parts of sulphur, 7.49 parts of wood charcoal, 10.97 parts of beech-wood sawdust, 1.65 parts of picric acid, 0.55 parts of water. The following figures as to the quantity of explosive required for 1 cubic metre of stone show that in compact rock, chamber mines, in which the quantity of explosive fired at one time is very large, are by far the most economical but in a non-compact formation the plan of bore-holes gives the best results. The quantity of diorexine required for 1 cubic metre of stone was:—

	With bore holes K.	With chamber mines. K.
In Prelucea (compact formation) ..	0.369	0.290
In Martinschizza (loose formation). 0.278	0.278	0.485
Zurkovo (loose formation) .....	0.199	0.522

For the production of the cavities for the smaller chamber-mines, advantage was taken of the action of hydrochloric acid upon the limestone. The acid was introduced into the bore-hole by means of a copper tube, and when a sufficiently large cavity had been eaten out, was withdrawn, and used repeatedly in new bore-holes until it was nearly neutralised. The plan was found to be very simple, but more tedious and expensive than the usual method of blasting out the required chamber with a small quantity of dynamite. In blasting submerged rock the expense of and time occupied in preparing bore-holes to receive the charges is no inconsiderable item of the whole undertaking. Lawer (*Mittheilungen über Gegenstände des Artillerie- und Genie-Wesens*, 1882, 1, and 1883, 437), taking advantage of the resistance offered to the explosive force by a considerable weight of water, has employed, with success, unconfined charges simply placed upon the surface of the rock. The blasting proceeded along the rock in a direction contrary to that of the current, so that the loosened masses were for the most part swept down the stream. An anchored barge, with projecting scaffold, was provided with a long beam or ram movable in the direction of its length upon the scaffold. Sockets were placed at equal distances upon the ram, and in any of the sockets could be fixed a long rod of iron tube suspended by a chain or wire rope. This rod carried the explosive at its lower end and could place it in almost any position, seeing that both the rod and the ram were movable, the one in a vertical, the other in a horizontal, direction. The chain or wire suspending the iron rod was passed over a pulley to a windlass, and so brought the rod completely under control. By this method of submarine blasting the consumption of explosive was greater than when the system of bore-holes was adopted, but the extra expense in this item was much more than counterbalanced by the saving in time and labour. From experiments recently made in America, interesting information as to the time elapsing between the explosion and its visible effect in blowing up a wreck has been obtained by photography. In 0.1 second after the explosion the vessel was broken up, and a column of water 20 metres high projected; in 1.5 seconds thereafter the column of water was 50 metres in height; in 2.3 seconds after the explosion shattered fragments and a column of water 60 metres in height were projected; in 3.3 seconds the water thrown up returned to the level, and after a total period of 4.3 seconds all was over.—W. D. B.

## New Books.

**FUEL AND WATER, WITH SPECIAL CHAPTERS ON HEAT AND STEAM BOILERS:** A Manual for Users of Steam and Water. From the German of Franz Schwaebkhofer, Professor at the Imperial and Royal School of Agriculture, Vienna. Edited by WALTER R. BROWNE, M.A., M.Inst.C.E., late Fellow of Trinity College, Cambridge. With numerous Illustrations. London: Chas. Griffin and Company, Exeter Street, Strand.

AN 8vo volume, bound in black cloth, with Editor's preface of 1½ pages, table of contents, introductory chapter by the Editor of 18½ pages, and subject matter filling 229 pages. An alphabetical index concludes the work. With the text are interspersed 85 woodcuts and numerous tables. The headings of the various chapters are as follows:—Part I. Fuel: Introductory Chapter on Heat and Combustion. Chap. i., Physical Characteristics of Heat (Temperature, Specific Heat, Conduction, Condensation, etc.); ii., Fuel (varieties); iii., The Firing Arrangements: The Furnace, The Flues, The Chimney, Useful Effect of Furnaces (with Examples of Calculations); iv., The Boiler: General Construction of Boilers, Choice of Steam Boilers, The Simple Cylindrical Boiler, The Compound Cylindrical Boiler, The Internally-fired Boiler, The Fire-tube Boiler, The Ten-brink Boiler, The Water-tube Boiler, Safety Fittings to Boilers, Boiler Explosions, Feed-water Heaters, Steam Pipes. Part II. Water: Chap. i., Physical Properties of Water; ii., Composition of Natural Waters; iii., Influence of the Composition of Water on its Application; iv., Purification of Water; v., Production of Cold and of Ice.

**ADDENDUM.**—Woodcuts illustrating the apparatus referred to in the article "On the Examination of Petroleum," pages 161 and 162, will appear in the April number of the Journal.

## Monthly Patent List.

### ENGLISH APPLICATIONS.

1881.

3542 J. Clark, Ph.D., Glasgow. Improvements for preventing the corrosion of iron articles by acids, salts, moisture, gases, or vapours. February 15  
3553 H. McGillivray, Clayton. Apparatus for diffusing gases through liquids used in depriving them of their hydrocarbons. February 19  
3558 J. Clark, Ph.D., Glasgow. Improvements in extracting nickel from its ores. February 19  
3599 A. J. Boulton, London. Improvements in machines for reducing ores. Communicated by G. Raymond and A. Raymond, Chicago, U.S.A. Complete specification. Feb. 19  
3615 R. Baynes, Liverpool, and A. Bigland, Liverpool. Improvements in treating, refining, or bleaching cotton-seed and other oils. February 20  
3612 P. M. Justice, London. Improvements in furnaces for calcining or burning cement. Communicated by Carl Dietzsch, Malsatt, Germany. February 20  
3644 M. A. F. Mennons, Paris. An improved compound for the prevention of incrustations and of galvanic action in steam boilers. Communicated by R. de Martino, Meta, Italy. February 20  
3656 J. B. Alliot, London. Improvements in treating liquid or other materials to concentrate and dry the same, and apparatus therefor. February 20  
3660 J. Buser, Marseilles. An improved non-conducting composition. Complete specification. February 20  
3673 C. Wigg, Liverpool, and J. Waller Pratt, Runcorn. Improvements in the manufacture of soda and chlorine. February 21  
3686 H. Gerhartz, Cologne, Germany. A new process of manufacturing liqueur out of milk. February 21  
3697 J. Miles, London. A new or improved method of treating certain materials for obtaining therefrom a powder for polishing or burnishing surfaces and for other purposes. February 21  
3723 W. Lloyd Wise, London. Improvements in the manufacture of saccharic acids. Communicated by the Chemische Fabrik Vormals, Hofmann and Schoetensack, Ludwigshafen, Germany. February 21  
3733 A. K. Huntington, London. A new or improved method and apparatus for separating mixed gases. February 21  
3736 W. A. Byrom, Wigan, and J. A. B. Bennett, King's Heath. Improvements in the method of taking off the volatile products from coal, shale, and other hydrocarbons during the process of distillation. February 22  
3760 I. Frankenburg, Salford. Improvements in the manufacture of waterproof cloth. February 22

3766 H. H. Hazard, London. The condensation and absorption of the products of combustion from coal or other gas or oil used either for lighting or heating purposes. February 22  
3780 Baron L. M. Dulfus, London. Improvements in the preparation of unflammable pulp for the manufacture of paper and for other purposes. Communicated by Julien Ponty, Brussels. February 22  
3786 Baron L. M. Dulfus, London. Improvements in means for rendering objects incombustible. Communicated by Julien Ponty, Brussels. February 22  
3790 H. W. Kuemeyer, Varel-on-the-Jade, Germany. Improvements in the treatment of fibrous materials for the preservation thereof. February 22  
3798 A. M. Clark, London. An improved process of and apparatus for separating and purifying certain components of the washings or scourings of wool and product obtained therefrom. Communicated by A. M. Hall, New York, U.S.A. Complete specification. February 22  
3807 F. Pidduck, Heywood. An improvement in the preparation of black lead for polishing and preserving the surface of iron. February 23  
3808 F. Wirth, Frankfurt-on-Main, Germany. Improvements in the manufacture of artificial stones, especially artificial lithographic stones and other similar bodies. Communicated by L. Rosenthal, Frankfurt-on-Main. February 23  
3836 John and James Addie, Glasgow. A new process of oxidising sulphites and hyposulphites. February 23  
3839 G. Patchett, Stockton-on-Tees; J. Dixon, Skelton-in-Cleveland; and R. Teasdale, Darlington. Improvements in means or apparatus for the manufacture of bricks, paving blocks, or the like, from the slag or scoria of blast furnaces. February 23  
3842 F. Wirth, Frankfurt-on-Main. Improvements in treating malt husks for certain industrial purposes. Communicated by P. Ammann, Munich, Germany. February 23  
3843 W. T. Read, Kentish Town. The treatment and preservation of beer. February 23  
3848 A. M. Clark, London. An improved process of and apparatus for extracting juice and crystallised sugar from the refuse or bagasse of sugar-cane and from any other part containing saccharine matter. Communicated by T. Blossom Yale, Columbia, Texas, U.S.A. February 23  
3855 J. King, junior, Manchester. Improvements in apparatus for taking off the gas from gas retorts and delivering it into the hydraulic main. February 25  
3870 J. F. Belfield, Exeter. Washing and purifying coal gas. February 25  
3882 E. Capitaine, London. Improvements in the manufacture of starch. Communicated by Drumm and Company, Kaiserslautern, Germany. February 25  
3964 Leon Barbier, Paris. Improvements in the manufacture of glucose. Complete specification. February 26  
3968 G. W. von Nawrocki, Berlin. A method of and apparatus for distilling ammoniacal fluids in a continuous manner. Communicated by Dr. P. Seidler, Elberfeld, Germany. February 26  
3987 W. T. Walker, Highgate. Improvements in condensing apparatus for purifying coal gas. February 26  
3995 J. Sandeman, Glasgow. Improvements in oleaginous compounds for preparing or treating textile materials or fabrics of cotton or other vegetable fibres for receiving or retaining colouring matters, or other purposes. February 27  
3996 F. Groom Redman, Peterborough, and J. Butt, Newark. Making sewage refuse into artificial manure. February 27  
4002 R. Hannan, Glasgow. Improvements in explosives for firearms, for blasting, and for similar purposes. February 27  
4003 L. A. Brode, Glasgow. The rendering of linen or calico impervious to water and heat. February 27  
4028 W. J. Chrystal, Glasgow. Improvements in the manufacture of bichromate of soda. February 27  
4065 Ivan Levinstein, Manchester. A new or improved method of preparing nitro-aniline and its homologues and nitronaphthylamines. February 28  
4102 S. Pitt, Sutton. Improvements in the manufacture of bichromate of potassa and other chromates. Communicated by H. Pemberton, Philadelphia, U.S.A. February 28  
4115 H. Whitehead and R. Hodgson, Eitley Heath, Cheshire. A new and improved method of and automatic apparatus for making common and fishery salt from brine by steam. February 29  
4122 J. McCulloch, Airdrie, N.B., and T. Reid, Glasgow. Improvements in coke ovens or retorts, and in apparatus connected therewith. Complete specification. February 29  
4127 H. H. Waddington, Manchester. Improvements in waterproof fabrics. Complete specification. February 29  
4178 J. Ballantyne Hannay, Cove Castle. Improvements in means or apparatus for removing lead from water. March 1  
4182 E. T. Pemberton, Liverpool. Improvements in brewing or producing ale and porter. March 1  
4195 and 4198 C. S. Gorman, Irvine. Improvements in the manufacture of bichromate of soda. March 1  
4201 A. Fiegl, Berlin. Management of fibre stuffs by a solution of sulphurous acid, which is mixed with muriatic or acetic acid, in order to the action. March 1  
4202 J. Foulis, Mussulburgh, N.B. Improvements in the methods or process of and apparatus for draining, concentrating, clarifying, and solidifying or consolidating substances and liquids, especially applicable for filtering paper-mill sludge and consolidating the substances contained therein. March 1  
4207 R. H. Hepburn, Westminster. Improvements in the means and apparatus for supplying steam and air, or air alone, to furnaces to cause more perfect combustion of fuel. March 1  
4241 F. W. Pittuck, Hebburn, and J. M. Hucklebridge, Jarrow. An improved method of purifying metallic copper in the presence of arsenic or antimony, or both. March 3

- 1268 S. Gilchrist Thomas, Westminster. Improvements in the manufacture of alkalis and alkaline salts. March 3
- 1273 Shirley Bowden, Holborn. A new or improved method of producing biphosphates of a high percentage from the slag resulting from dephosphorising iron by the basic process and from natural phosphates. Communicated by H. Schliwa, Waldeck, Germany. March 3
- 1285 H. H. Lake, London. Improved means for generating steam by chemical agents. Communicated by H. Grunberg and E. Hardt, Cologne. Complete specification. March 3
- 1286 A. J. Boulton, London. Improvements in regenerative coke furnaces. Communicated by the Schlesiische Kohlen und Cokeswerke, Gottesberg, Germany. March 3
- 1301 A. M. Clark, London. Improved apparatus for agitating the liquid in liming vats. Communicated by J. B. McEnally, Clearfield, Pennsylvania, U.S.A. March 3
- 1312 J. Walker Newall, Ongar. Improvements in regenerative furnaces. March 4
- 1313 J. Walker Newall, Ongar. Improvements in kilns for burning bricks and other earthenware goods. March 4
- 1325 R. A. Mossman, and J. Mayel Mayelston, Elloughton, Yorks. Improvements in the manufacture or preparation of aerated liquids of all kinds, and of the bicarbonates of potash, soda, and ammonia, and likewise of the sesquicarbonates of potash and soda. March 4
- 1333 J. Miles, London. A new or improved method of extracting metals from the material found combined with coal, commonly known as ironstone. March 4
- 1348 H. J. Haddan, Westminster. Improvements in anti-fouling, anti-corrosive, and preservative paints. Communicated by W. Denison Folger, Calcutta. Complete specification. March 4
- 1356 Dr. T. Weyl, Berlin. Improvements in the production of caseine peptone and peptonised milk. March 4
- 1361 A. D. Cohen and H. J. Emanuel, London. Improvements in the employment of substances and in the means of producing cold, which is also applicable for other purposes. March 4
- 1362 F. Wirth, Frankfort-on-the-Main, Germany. Improvements in the manufacture of cream of tartar. Communicated by F. Dietrich, Munich, Germany. March 4
- 1392 A. Adair, Egremont, Cumberland. Improvements in the manufacture of phosphates and phosphoric acid. March 5
- 1397 R. Howarth, Wolverhampton. Improvements in apparatus for condensing steam or other vapours. March 5
- 1403 T. Welton, London. Improvements in deodorising faecal matter in water-closets, urinals, and similar places. March 5
- 1410 J. C. Mewburn, London. Improvements in dyeing and otherwise operating upon fibrous materials when in the form of silvers, skeins, or warps, and in machinery employed therein. Communicated by J. Stoltz, Roubaix, Nord, France. March 5
- 1415 G. W. Von Nawrocki, Berlin. A method of manufacturing new pigments. Communicated by P. Bottiger, Lodz, Russia. March 5
- 1417 W. S. Richardson and W. J. Grey, Gateshead. Improvements in the treatment of chloride of sodium for the production of bleaching powder and other materials therefrom. March 5
- 1452 G. C. Denison and J. E. Higgin, Northwich. Improvements in and relating to the manufacture of salt from brine and apparatus therefor. March 6
- 1480 W. L. Wise, London. The manufacture of mordants and colouring matters from glucosides, tannin, and bitter principles. Communicated by C. H. Knoop, Dresden. March 6
- 1482 J. H. Johnson, London. Improvements in cementation furnaces. Communicated by A. Berthomieu, Paris. March 6
- 1516 W. Scott, Glasgow. Improvements in the recovery of ammonia from waste gases. March 7
- 1533 H. A. Dufrene, Paris. Improvements in apparatus for cooling beer and other liquids. Communicated by N. Dubouche, Sedan, France. March 7
- 1632 C. A. Caspersson, Forsbacka, Sweden. Improvements in the process of pouring and casting iron, steel, and other metals. Complete specification. March 10
- 1650 H. J. Haddan, London. Improvements in apparatus for treating textile materials with liquids or gases. Communicated by O. Obermaier, Lambrecht, Bavaria. March 10
- 1652 H. H. Lake, London. Improvements in kilns or furnaces for burning bricks, lime, and similar materials. Communicated by W. Eckardt, Dortmund, Germany. March 10
- 1663 C. H. Greville Williams, Hounslow. Process for the separation of benzene and its homologues from the liquid obtained by compression of petroleum gas. Complete specification. March 10
- 1679 B. Davy, Keighley, Yorkshire. An improved method for extracting grease from soap water. March 11
- 1681 L. Poensgen, Dusseldorf, Prussia. Improved process for putting tin-plate refuse in hermetically-closed apparatus, and at the same time obtaining ammonia. Complete specification. March 11
- 1690 F. Hocking, Liverpool. Improvements in and relating to apparatus for condensing and cooling, particularly applicable for the production of fresh water from salt water. March 11
- 1698 W. H. Spence, London. An improved method of utilising the waste residues of fuel. Communicated by F. W. C. Waldeck, The Hague, Netherlands. March 11
- 1707 J. B. Thompson, New Cross, Kent. Improvements in bleaching. March 11
- 1708 A. M. Chambers, Thornecliffe, and T. Smith, Chapeltown. Improvements in coke ovens, and in methods of and apparatus for collecting and utilising the products of combustion from such coke ovens. March 11
- 1711 Bruno Baron von Steinaecker, Lauban, Prussia. An improved manufacture of combustible gas for lighting and heating purposes, and in apparatus for this purpose, and for the application of such combustible gas to furnaces, ovens, kilns, steam boilers, and other industrial and domestic purposes. March 11
- 1716 A. W. L. Reddie, London. Improved evaporating or condensing apparatus. Communicated by E. Theisen, Lindenau, Germany. Complete specification. March 11
- 1718 W. Black, South Shields, and T. Larkin, East Jarrow. Improvements in furnaces for the manufacture of sulphate of soda or hydrochloric acid, or for roasting or calcining ores, or for analogous purposes. March 11
- 1726 C. D. Abel, London. An improved titration apparatus for alkalimetric and acidimetric determinations. Communicated by E. Groiner, Stutzerbach, Germany. Complete specification. March 11
- 1761 W. Weldon, Burstow, Surrey. Improvements in the manufacture of bicarbonate of soda. Partly communicated by A. R. Pechiney, Salindres, France. March 12
- 1755 R. Lehmann, London. A new or improved process for the manufacture of hydrogen. Communicated by J. Oetli, Cossonay, Switzerland. March 12
- 1792 A. Southwell, Southampton. An improved composition or compound for covering boilers, pipes, ice safes, and other like bodies. March 12
- 1796 P. Layden and W. McLean, Jarrow-on-Tyne. Improvements in priming and anti-fouling compositions. March 12
- 1808 T. Lowe, Old Radford, Nottinghamshire. Boiler composition. March 13
- 1811 W. J. A. Donald, Glasgow. Improvements in the manufacture of chromates and bichromates. March 13
- 1825 W. P. Wilson, London. Improvements in the manufacture of gas for illuminating purposes, and in apparatus or means to be employed therein. March 13
- 1826 W. J. Gale, Clifton, Gloucestershire. Improvements in treating leather for the purpose of rendering the same water-repellant, water-proof, and more durable. March 13
- 1830 J. H. Johnson, London. Improvements in the preparation of halogen derivatives of tetra-methyl-diamido-benzophenone and analogous ketone bases. Communicated by H. Caro, Ludwigshafen-on-the-Rhine, Germany. March 13
- 1833 J. Parker, Kilmarlock, N.B. Improvements in stoves, or apparatus for drying or heating bricks or other articles. March 14
- 1865 R. J. Atcherley, Ph.D., London. An improved method and apparatus for the amalgamation of free gold. March 14
- 1879 J. Watson, Greenhithe, Kent. Improved apparatus to be used in the manufacture or preparation of cement. March 14
- 1902 W. R. Lake, London. Improvements in apparatus for drying and superheating steam, and for similar purposes. Communicated by L. Fouque, Paris. March 14
- 1929 C. S. Gorman, Irvine, N.B. Improvements in the manufacture of bicarbonate of soda. March 15
- 1936 J. Hodgkins, Wednesbury, Staffordshire. Improvements in furnaces for melting metals by a new or improved process. March 15
- 1917 S. G. Thomas, Westminster and El Biar, Algeria. Improvements in the manufacture of phosphatic salts. March 15
- 1955 G. W. von Nawrocki, Berlin. A furnace for reducing zinc and other metals. Communicated by J. Quaglio, Frankfort-on-Main, Germany. March 15
- 1961 C. D. Abel, London. The production of violet and blue colouring matters of the rosaniline series by treating aromatic amines with alkylised amido derivatives benzoylchloride and of benzophenone. Communicated by Farbwerke Vormals Meister, Lucius, and Bruning, Höchst-on-the-Main, Germany. March 15
- 5002 C. W. Rees, London. Improvements in treating wooden articles so as to give them the appearance of metal, and compositions therefor. March 17
- 5021 F. Wirth, Frankfort-on-the-Main. Improvements in colouring matters. Communicated by Prof. E. Erlenmeyer, Frankfort-on-Main, Germany. March 17
- 5025 S. R. Smyth, London. Improvements in smelting iron ores, and in the apparatus employed therein. March 17
- 5038 J. H. Johnson, London. Improvements in the preparation of colouring matters suitable for dyeing and printing from halogen derivatives of tetra-methyl-diamido-benzophenone and analogous ketone bases. Communicated by H. Caro, Ludwigshafen-on-the-Rhine, Germany. March 18
- 5056 H. Brewer, junior, Manchester, and W. A. Brewer, Crumpsall. Improvements in and material for producing a deep black polish upon wood, leather, lacustrawalton, metal work, and other surfaces. March 18
- 5070 R. Kennedy and W. Fairweather, Glasgow. Improvements in bleaching. March 18
- 5071 R. Kennedy and W. Fairweather, Glasgow. An improved method of oxidising sulphites and hyposulphites. March 18
- 5082 W. R. Lake, London. Improvements in machines for breaking or crushing stone, ore, and similar materials. Communicated by T. A. Blake, New Haven, U.S.A. March 18
- 5089 A. J. Bonlt, London. Improved continuous malt-kiln. Communicated by H. A. Kolndorfer, Vienna, Austria. March 18
- 5096 F. Settle Barff, Kilburn. Improvements in the treatment of liquids and substances which are subject to fermentation. March 18

21/- per Set; Single Copies 2/6.

## COUNCIL.

*President:* Walter Weldon, F.R.S.

*Vice-Presidents who have filled the Office of President:*  
Sir Frederick Abel, C.B., D.C.L., F.R.S.  
Professor H. E. Roscoe, Ph.D., LL.D., F.R.S.

*Vice-Presidents:*

I. Lowthian Bell, F.R.S.  
George E. Davis.  
J. H. Gilbert, D.C.L., F.R.S.  
F. H. Gossage.  
D. B. Hewitt, M.D.

David Howard.  
E. K. Misparratt.  
H. Lee Pattinson.  
W. H. Perkin, Ph.D., F.R.S.  
Prof. James Dewar, F.R.S.

*Ordinary Members of the Council:*

Eustace Carey.  
Alexander M. Chance.  
Prof. Chas. Graham, D.Sc.  
Peter Griess, Ph.D., F.R.S.  
James Maclear.  
R. Messel, Ph.D.

John Pattinson.  
B. S. Proctor.  
R. Angus Smith, Ph.D.,  
F.R.S.  
John Spiller.  
John Williams.  
P. J. Worsley.

With the Chairmen and Secretaries of Local Sections.

*Honorary Treasurer:*

E. Rider Cook, East London Soapworks, Bow, E.

*Honorary Foreign Secretary:*

Ludwig Mond, Winnington Hall, Northwich.

*General Secretary:*

Charles G. Cresswell, Palace Chambers, 9, Bridge Street,  
Westminster.

## THE JOURNAL.

*Publication Committee:*

*The President.*

Sir F. A. Abel, F.R.S.  
Joseph Bernays.  
Eustace Carey.  
W. Lant Carpenter.  
George E. Davis.  
Prof. Dewar, F.R.S.  
Chas. Ekin.  
Prof. Chas. Graham, D.Sc.  
Peter Griess, Ph.D., F.R.S.  
D. B. Hewitt, M.D.  
David Howard.  
Prof. A. K. Huntington.  
F. Hurter, Ph.D.

E. W. T. Jones.  
Raphael Meldola.  
Ludwig Mond, Ph.D.  
Chas. O'Neill.  
C. O'Sullivan.  
John Pattinson.  
Prof. H. E. Roscoe, F.R.S.  
Prof. C. Schorlemmer,  
F.R.S.  
John Spiller.  
A. Norman Tate.  
Thomas Tyrer.

*Editor:* Watson Smith.

ASSISTED BY THE FOLLOWING STAFF OF  
*Abstractors:*

A. H. Allen.  
H. Baker.  
D. Bendix.  
E. J. Bevan.  
G. B. Bostock.  
W. Bott, Ph.D.  
W. Dalrymple Berland.  
J. T. Brown.  
Robt. Commins.  
E. G. Clayton.  
C. F. Cross.  
A. R. Davis.  
J. Grossman, Ph.D.  
J. J. Hummel.  
C. C. Hutchinson.

H. A. Rademacher.  
F. W. Renaut.  
A. Smithells, B.Sc.  
James Taylor, B.Sc.  
Alex. Watt.  
Otto N. Witt, Ph.D.  
Sydney Young, D.Sc.

*Japanese Correspondent:* T. Takamatsu.

## NOTICES.

In accordance with the provisions of the 9th by-law, notice is hereby given that those members whose names are placed in italics in the annexed list of Council will retire from their respective offices at the forthcoming Annual General Meeting.

Members are hereby invited to nominate fit and proper persons to fill the four vacancies thus created among the Ordinary Members of the Council, in accordance with the terms of the 9th, 11th, and 12th by-laws.

The bye-laws are inserted in the number of the Journal for July, 1883. They can also be obtained from the Secretary, who will supply the prescribed nomination forms upon application.

## ANNUAL GENERAL MEETING.

The next Annual General Meeting of the Members of the Society of Chemical Industry will be held at Newcastle-on-Tyne, on Wednesday, Thursday, and Friday, the 9th, 10th, and 11th of July next.

It is proposed that the morning of Wednesday, the 9th of July, shall be devoted to the transaction of the ordinary business of the Society, the election of office bearers, and an Address by the President; that on Wednesday afternoon the Members shall visit various Works; and that in the evening those of the Members attending the Meeting who choose to do so shall dine together. By the kind permission of Sir WILLIAM ARMSTRONG, K.C.B., the dinner will take place in the Banqueting Hall at Jesmond Dene. The dinner tickets will not include wine, for which separate arrangements will be made.

It is proposed that on Thursday, the 10th of July, the Members shall meet in the morning for the discussion of papers by Mr. W. S. SUTHERLAND, Mr. GEORGE BEILBY, Mr. JAMESON, and, it is hoped, Mr. HENRY SIMON, and perhaps others, on the treatment of coal for the obtainment therefrom of condensable volatile products; and that in the afternoon they shall visit various Works.

In the evening a *Conversazione* will be held.

It is proposed that Friday, the 12th of July, shall be entirely devoted to visits to various Works. It is intended that a special steamer shall convey the Members in the morning down the Tyne to the Work to be first visited, and that in the course of the afternoon the Members shall have an opportunity of proceeding by this steamer as far as Tynemouth pier, so that they may see the whole of the Tyne between Newcastle and the sea.

The meetings on the mornings of Wednesday and Thursday will take place in the Lecture Theatre of the Literary and Philosophical Society. The Wood Memorial Hall of the North of England Mining Institute will be available during the Meeting as a Reception and Writing Room. The Library of the Literary and Philosophical Society will also be available as a Writing Room.

Various Works in the district, in addition to those to which visits will be specially organised, will be open to Members during the Meeting on presentation of their cards of Membership.

Opportunities of seeing in operation the SIMON-CARVÉ process, and the JAMESON process, will be afforded during the Meeting.

Messrs. BAIRD & Co. have consented that any Members attending the Meeting who choose to proceed to Gartsherrie for the purpose, shall see the process at work there for obtaining ammonia from the gases from blast-furnaces; and Messrs. YOUNG and BEILBY have promised to show their process at two Works near Edinburgh.

Full details of the arrangements for the Meeting will be published in the June number of the Journal.

Numerous inquiries have been made for sets of the Journal for 1882. Some of the numbers for that year are out of print. Members who have not the volume for 1882, and wish to obtain it, are invited to signify that wish to the Secretary as early as possible. If a sufficient number of applications for that volume are received, the missing numbers of it will be reprinted.

The Proceedings of the First General Meeting (1881) of the Society of Chemical Industry have been reprinted in such size and style as to permit of their being bound up with the Journal. Copies of the reprinted Proceedings will be forwarded by the Publishers on receipt by them of twelve penny stamps for each copy required.

**NOTICE TO MANUFACTURERS AND OTHERS.**—In consequence of numerous inquiries, attention is called to the fact that the price of extra sets of the Journal to members is one guinea, whether such sets are for the current year or for past years. A misapprehension on this score appears to have deterred certain members from applying for duplicate copies for official and laboratory use.

Authors of papers printed in the Journal are hereby notified of the fact that, in accordance with bye-law 36, they are entitled to receive not more than 50 gratuitous copies of their papers. Authors should state on their manuscripts their desire to have free copies, adding the number wished for. Unless the contrary be specially desired, this being stated on the manuscript, the reprints of an author's paper will not include the report of any discussion that may have arisen after the reading of the paper.

#### LIST OF MEMBERS ELECTED APRIL 24th, 1884.

Henry Aitken, Danoch, Falkirk, N.B., mining engineer.  
C. Torre Anderson, Messrs. Bass and Company, Burton-on-Trent, brewer.  
John Anderson, 133, Bath Street, Glasgow, analytical chemist.  
James M. Bennett, 12, Hamilton Drive, Hillhead, Glasgow, metallurgist.  
J. William Biggart, 29, Cathcart Street, Greenock, N.B., analytical chemist.  
Charles Blatherwick, Dunaivon, Helensburgh, N.B., Government inspector alkali works.  
G. H. Bostock, 9, Great John Street, Manchester, analytical chemist.  
Henry T. Bottinger, Elberfeld, Germany, director of the Farbenfabrik. (See form.)  
Charles Jul. Caspers, care of Messrs. Read, Holliday, and Sons, Huddersfield, commercial manager.  
Frederick Cheshire, Laboratory, Somerset House, London, W.C., assistant analyst.  
Saml. Crowder, Stafford Lodge, Anerley Park, London, S.E.  
Thomas Dawson, Stonecroft House, Milnsbridge, near Huddersfield, aniline dye manufacturer.  
Geo. Dyson, Sockburn, Darlington, chemical manufacturer.  
James Donald, 3, Queen's Terrace, Glasgow, manufacturing chemist.  
Thomas Felton, 217, Brook Road, Upper Clapton, London, E., manager oil distillery.

J. T. J. Findlay, Silvertown, London, E., Chemist.  
J. J. Finlay, 53, Renfield Street, Glasgow, analyst and assayer, Tharsis Company.  
Daniel Frazer, 113, Buchanan Street, Glasgow, pharmacist.  
A. R. Gillespie, 20, Lomond Road, Trinity, Edinburgh, director oil company.  
F. Haddkinson, Pamphila Oil and Soap Works, Mitylene, Mediterranean.  
G. J. Hamlen, Oakbank Oil Works, Midcaldor, N.B., chemist.  
Wm. Hawdon, care of Samuelson and Co., Newport Iron Works, Middlesbrough.  
Z. J. Heys, Stonehouse, Barrhead, N.B., calico printer.  
T. G. Hunter, 81, Thistle Grove, South Kensington, chemist.  
G. H. Hurst, 11, Cable Street, Salford, Manchester, analyst and lecturer.  
Alex. Johnstone, Chemical Laboratory, Blairlodge School, Polmont Station, N.B.  
Samuel Knowles, Stormer Lodge, Crumpsall, Manchester, calico printer.  
Nigel Macphie, Clippens Oil Works, by Johnstone, N.B. cashier.  
A. J. Higgin, Little Peter Street, Manchester.  
William Marshall, Eddlewood, Hamilton, N.B., ironworks chemist.  
William G. O'Beirne, 15, Campbell Street, Mary Hill, Glasgow, analyst.  
J. Edgar Poynter, Clydeneuk, Uddingston, N.B., manufacturing chemist.  
H. A. Rademacher, Turn Lee Paper Mills, Charlestown, Glossop.  
R. Andrew Robertson, 42, Aytoun Road, Pollokshields, Glasgow, mechanical engineer.  
Albert E. Reed, Ely Paper Works, Cardiff.  
Adolphe Roques, 36, Rue Sainte Croix de la Bretonnerie, Paris, chemical manufacturer.  
Prof. Samuel P. Sadtler, F.C.S., University of Pennsylvania, Philadelphia, Pa., U.S.A.  
Walter Shaw, Sherdley Glass Works, St. Helens, glass manufacturer.  
Hubert C. Shorten, 8, Hetley Road, Uxbridge Road, London, W., student.  
R. Simpson, Grecian Terrace, Harrington, Cumberland, chemical student.  
George Smith, Ravensdene, Sutton, Surrey, manufacturing chemist.  
J. Stevenson, Broxburn, N.B., assistant chemist in oilworks.  
George Swinburne, 33, Frederick Street, Gray's Inn Road, London, W.E., gas engineer.  
G. Carruthers Thomson, 77, Hill Street, Garnet Hill, Glasgow, engineer.  
Jno. Thomson, Institution for Deaf and Dumb, Queen's Park, Glasgow.  
R. Tatlock Thomson, 138, Bath Street, Glasgow, analyst.  
W. Spencer Turner, 225, Oxford Street, Manchester, pharmacist.  
G. Watson, jun., 318, St. Vincent Street, Glasgow, manufacturing chemist.  
A. Wilson, 3, Victoria Place, Trinity, Edinburgh, manager.  
W. Wright, Fairfield Road Chemical Works, Droylsdale, Manchester.  
Edwin Addenbrooke, 18, Cawley Road, South Hackney, assistant chemist Metropolitan Board of Works.  
H. J. Barnes, Phoenix Chemical Works, Hackney Wick, manufacturing chemist.  
W. H. Booth, Lonsdale, Flixton, near Manchester, consulting engineer.  
Thomas Dearden, 12, Heywood Street, Bury, Lancashire, technical chemist.  
J. R. Fletcher, Kersley Paper Mills, Stonecrough, Manchester, paper maker.  
W. E. Heys, Milton Terrace, Everton Road, Manchester, electrical engineer.  
J. M. Irving, 6, Booth Street, Piccadilly, Manchester, chemical merchant.  
John Paterson, Derwent Villa, Workington, Cumberland, mechanical engineer.  
Walter V. Robinson, 6, Market Buildings, Mincing Lane, London, E.C., chemical merchant.  
Ferd. Rohling, 65, Nelson Street, Oxford Road, Manchester, technical chemist.  
A. G. Salaman, Thornton House, Clapham Park, London, S.W., consulting chemist.  
C. H. Saul, 76, Mosley Street, Manchester, drysalter.  
Julius Schadt, 11, Charlotte Street, Manchester, agent for aniline company.  
J. Sellars, Fairfield, near Manchester, manufacturing chemist.  
T. R. Shaw, Mill Street Works, Pendleton, Lancashire, oil merchant and dyer.

#### CHANGES OF ADDRESS, ETC.

*A List of Changes of Address follows the List of New Members for the information of the Society's officers and others. The General Secretary trusts that members will second his efforts to make this List a complete and accurate record by notifying to him their changes of address as promptly as possible.*

Angus, John (late of Fenchurch Avenue), 47, Lime Street, London, E.C.  
Barnes, R. L. (late of Buckhurst Hill), Lancaster House Savoy, London, W.C.

Boucart, Robt. (late of Manchester), à la Boissière, près Genève, Suisse.

Brown, J. T. (late of King's Road), 3, Dartrey Road, Chelsea, London, S.W.

Clift, Jas. (late of Jervoise Street), Billhay Street, West Bromwich.

Cox, John (late of Mulheim), Hunstanton St. Edmonds, Norfolk.

Duggan, T. R. (late of South Hackney), 11, Alkham Road, Stoke Newington, N.

Gibbs, W. P. (late of Darlington), care of Messrs. Newton, Keats, and Company, Sutton, St. Helens.

Hulme, James (late of Macclesfield), Owens College, Manchester.

Irwin, J. T. (late of Blackburn), 177, York Street, Cheetham Hill, Manchester.

King, A. J. (late of Mining Lane), Ingersley Vale Bleach-works, Bollington, near Macclesfield.

Laws, J. P. (late of Highgate Hill), 3, Tyfield Road, Oxford.

Miller, John, 151, Glenpark Street (not Gunport Street as given), Glasgow.

Walker, H. W., 37, Fox Street, Greenock, N.B.

## London Section.

*Chairman:* David Howard.

### *Committee:*

Sir F. A. Abel.	R. E. R. Newlands.
H. E. Armstrong.	B. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewby.
A. K. Huntington.	W. Weldon.
R. Messel.	J. Williams.

*Local Sec.:* Thos. Tyrer, Garden Wharf, Church Road, Battersea, W.

The remaining meetings of the session will be held as follows, when papers will be read by—

On May 5th, Dr. Percy Frankland, "On the Composition and Illuminating Power of Coal Gas." Mr. W. J. Dibdin, "On the Estimation of the Illuminating Power of Gas Burners, especially those of large size."

On June 9th, Mr. W. S. Squire, "On the Processes Concerned in the Conversion of Starch into Alcohol, and their relation to Brewing and Distilling," illustrated.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE,

Monday, April 7th, 1884.

MR. DAVID HOWARD IN THE CHAIR.

The election of the local sectional committee took place, with the result that the committee as printed above were elected to serve for the next three years.

## THE ESTIMATION OF SULPHUROUS ACID IN ITS COMPOUNDS.

BY W. B. GILES AND A. SHEARER.

THE object of the investigation which forms the subject of the present paper was to examine the methods used in determining the sulphurous acid existing in the combinations of that acid which are of industrial importance. The method generally employed is that given by Fresenius in his "Quantitative Chemical Analysis," based upon Bunsen's well-known reaction between iodine and sulphurous acid in very dilute solutions. This method, if carried out strictly according to Fresenius's instructions, leaves little to be desired on the score of constancy of results, although they are generally a little low. The great objection to it, however, is the large dilution with air-free water which is necessary. It is almost impossible to obtain water *absolutely* free from air, and the difficulty of obtaining and preserving it as nearly pure as

possible is very considerable, and even where only an occasional analysis of sulphurous acid or its compounds is made involves much preliminary trouble and loss of time; while if a number of such determinations have to be made daily the difficulty becomes so great as to render a shorter and equally accurate process very desirable. The authors first investigated the means of estimating the sulphurous acid in the normal sulphites. Sulphite of sodium was selected as a type of these salts. The sample operated upon was prepared with great care from a crystallisation of several tons, and was the same for the entire series of experiments, it having been found hardly possible to prepare a sample sufficiently pure on the laboratory scale. The authors take this opportunity of thanking Messrs A. Boake and Company, of Stratford, for their kindness in affording them every facility in obtaining the samples, etc. The salt was first analysed gravimetrically, in order that a basis of comparison might be obtained, and, as will be seen from the following results, was nearly pure, having a composition closely agreeing with the formula  $\text{Na}_2\text{SO}_3 + 7\text{H}_2\text{O}$ . It may here be remarked that the authors' experience points to the foregoing formula as invariably representing the composition of crystallised sulphite of sodium. The salt mentioned by Muspratt, having the composition  $\text{Na}_2\text{SO}_3 + 10\text{H}_2\text{O}$ , has never been noticed by them during a lengthened experience of the crystallisation of the salt on a very large scale and under greatly varying conditions of temperature, concentration, and other influences such as acidity or alkalinity of the mother-liquors. These observations agree with those made by Rammelsberg and Schultz Sellack. The following are the details of the methods followed in the gravimetric analysis of the sulphite.

1.  $\text{SO}_2$  and  $\text{SO}_3$  were estimated by oxidising 0.5grm. of the sulphite with bromine water, subsequently adding HCl and heating, precipitating with  $\text{BaCl}_2$  after nearly neutralising the solution with  $\text{NH}_3$ , filtering, and igniting and weighing as  $\text{BaSO}_4$ .

0.5grm. of sulphite gave 0.465  $\text{BaSO}_4 = 31.33\% \text{SO}_3$ .

2. The  $\text{SO}_3$  existing as such was estimated in from 2grms. to 2.5grms. by the following process: A flask was filled with recently-distilled water, and fitted with a rubber stopper carrying a glass tube drawn out to a fine point. The water contained in the flask was then heated to boiling, and kept so for two hours, when 10c.c. of HCl free from  $\text{SO}_3$  were added, and the boiling continued for half an hour longer. The quantity of sulphite used was now weighed in a small test tube, and the stopper of the flask being momentarily withdrawn the tube and its contents were dropped in, the stopper then replaced loosely. When the evolution of sulphurous acid had somewhat subsided the cork was firmly fitted, and the boiling was continued till every trace of sulphurous acid was expelled. The excess of HCl was then almost neutralised by  $\text{NH}_3$ , and the  $\text{SO}_3$  was precipitated and weighed as  $\text{BaSO}_4$ . Two determinations made in this way gave the following results:—

- (a) 2.161grms. sulphite gave 0.025grm.  $\text{BaSO}_4 = 0.397\% \text{SO}_3$ .  
 (b) 2.594grms. sulphite gave 0.0305grm.  $\text{BaSO}_4 = 0.403\% \text{SO}_3$ .  
 The two determinations giving as a mean 0.400%  $\text{SO}_3$ .

3. By deducting the  $\text{SO}_3$  found in (2) from that found in (1), the  $\text{SO}_3$  resulting from the oxidation of  $\text{SO}_2$  is obtained, and from this the percentage of  $\text{SO}_2$  calculated.

	Per cent.
Total percentage of $\text{SO}_3$ (1).....	31.33
$\text{SO}_3$ existing as such (2).....	0.40
$\text{SO}_3$ resulting from oxidation of $\text{SO}_2$ .....	31.53
Equal to 25.22% of $\text{SO}_2$ or $\text{Na}_2\text{SO}_3, 7\text{H}_2\text{O}$ ....	99.32%

4. The water of crystallisation and moisture was estimated by drying 1grm. in the water oven. During

the desiccation, however, the salt was found to undergo a slight oxidation. The amount of oxygen so absorbed was found from the difference in the iodimetric titre before and after drying. The following results were thus obtained:—

1grm. dried at 100° lost.....	0.4935grm.
1grm. of the undried sulphite required.....	79.2 } c.c. $\frac{n}{10}$ I.
1grm. of the dried sulphite required.....	76.5 }
Difference .....	2.7 c.c.

Calculated to oxygen the difference gives 0.0021grm. of oxygen absorbed during the drying, which amount has to be added to the observed loss of water, thus making the total loss of water 50.06 per cent.

5. The soda was calculated from the SO<sub>2</sub> and SO<sub>3</sub> found above, and the following figures embody the results obtained:—

Sample employed	Pure Na <sub>2</sub> SO <sub>3</sub> ·7H <sub>2</sub> O contains
SO <sub>2</sub> .....	25.22 .....
SO <sub>3</sub> .....	0.40 .....
Na <sub>2</sub> O .....	24.74 .....
H <sub>2</sub> O .....	50.06 .....
100.42	100.000

The sulphurous acid was next determined in another portion of the sulphite by the method given by Fresenius. Special precautions were taken to obtain air-free water for this estimation. The plan adopted was as follows: Two 60oz. flasks A and B were nearly filled with freshly distilled water, the contents heated to boiling, and the boiling continued for four hours. A rubber stopper, carrying a tube bent twice at right angles, one limb of the tube being short and the other long enough to reach to the bottom of the flasks, was now fitted to one of the flasks A, the short limb of the tube entering the flask and the long limb being plunged below the surface of the water in the flask B, the lamps being momentarily withdrawn. Matters so arranged, the lamp was placed below A and the boiling continued for an hour, the contents of the flask B being kept boiling by the steam passing through it. The boiling being then stopped the water in B was immediately covered with a layer of purified hydrocarbon oil to a depth of half an inch and the apparatus allowed to cool. As the cooling progressed a portion of the water in B receded into A, which was thus kept full and out of contact with air. A weighed portion of 0.5grm. of the sulphite was then dissolved in 250c.c. of the water from the flask A, and the solution poured with stirring into 40c.c. of  $\frac{n}{10}$  iodine solution, the whole operation being performed as quickly as possible to prevent absorption of oxygen from the air. It was found necessary to use 0.73c.c. of  $\frac{n}{10}$  thiosulphate to remove the excess of iodine. From this 0.5grm. of the sulphite consumes 39.27c.c. of  $\frac{n}{10}$  iodine, which calculated out gives 25.13 per cent. SO<sub>2</sub>, equal to 98.96 per cent. of Na<sub>2</sub>SO<sub>3</sub>+7H<sub>2</sub>O. The influence of dissolved oxygen in the water upon the results obtained, and also the extreme rapidity with which water takes up this oxygen, was well shown when a further determination was made with water from the same flask A, the stopper having been left out for a short time while the first trial was made, the same quantity of sulphite dissolved in the same quantity of water now giving 24.65 per cent. SO<sub>2</sub>, equal to 97.07 per cent. of Na<sub>2</sub>SO<sub>3</sub>·7H<sub>2</sub>O, or a loss of nearly 2 per cent. of sulphite in a few minutes. This very rapid change has been repeatedly noticed by the authors, and formerly sometimes led them to think that the variations between the iodine and the sulphite were caused by some irregularity in the reaction, until the true cause was detected. A num-

ber of estimations were then made, freshly distilled water being used instead of air-free water. In other respects the titration was carried out precisely as before.

TABLE 1.

G.....	0.5	1000.0	27.6	69.550

As some observers, Mohr for instance, recommend the addition of bicarbonate, another trial was made, adding 2grms. pure potassium bicarbonate to 500c.c. of water, and dissolving *before* adding the sulphite.

This was found to require 33.60c.c. of  $\frac{n}{10}$  iodine, showing that the addition of bicarbonate has no effect in preventing the oxidation. After considerable thought and experience the following method was devised by the authors, in order to render unnecessary the use of air-free water, and was found to give highly satisfactory and concordant results. A portion of the finely-ground sulphite was introduced into an ordinary stoppered weighing tube, and the weight noted. A measured quantity of  $\frac{n}{10}$  iodine was then run into a beaker from a fine burette. In some of the experiments water in varying quantity was added for the purpose of establishing the influence this addition had upon the results. It was found, however, that though no precaution was taken to free the water from dissolved oxygen, the addition of quantities equal to the dilution found to be necessary by Bunsen in carrying out the titration of sulphurous acid upon iodine, viz., .05 per cent. SO<sub>2</sub>, had no influence upon the result, and also that the addition of water might be dispensed with altogether. A portion of the sulphite in the weighed tube was gently shaken out of the tube directly into the  $\frac{n}{10}$  iodine without previously dissolving it in water, stirring during the addition until the yellow colour just vanished; a few c.c. of starch then being added, and  $\frac{n}{10}$  iodine dropped in until the blue colour appeared (not more than a few tenths of a cubic centimetre were required). A second weighing gave the exact amount of sulphite used. The results are given in the following table:—

TABLE 2.

The above figures show great accordance among themselves, and also with the percentages obtained both by the oxidation process and titration in diluted solution in air-free water. Throwing out the middle line in series D in the above table, the difference between the highest and lowest result is 0.07 per cent. of  $\text{SO}_2$ , or 0.28  $\text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O}$ . The mean of the eight results (discarding the highest one of series D as being an error of observation) is 25.15 per cent. of  $\text{SO}_2$ , or 99.03 per cent. of  $\text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O}$ . For comparison we tabulate the results by the three methods:

TABLE 3.

Method taken.	$\text{SO}_2$ % found.	$\text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O}$ found %.
By oxidation and subsequent precipitation with $\text{BaCl}_2$ after deducting $\text{SO}_2$ found.....	25.22	99.32
By Fresenius's modification of Bunsen's method.....	25.13	98.96
By method above given the mean of eight determinations.....	25.15	99.03

Another modification of the above process, although based upon the same principle, gave slightly higher results, and is preferred by the authors, inasmuch as every chance of outside oxidation is removed from beginning to end of the operation by employing an excess of iodine to start with. In this case 0.5 grm. of the sulphite was weighed on a watch glass, and the glass and its contents transferred at once to a beaker containing 40 c.c. of  $\frac{n}{10}$  iodine, and the whole well stirred with a glass rod. In some cases the iodine was diluted with a measured quantity of distilled water, but, as in the former experiments, this dilution did not have any influence. The results thus obtained are shown in the following table:—

TABLE 4.

Grammes of sulphite used.	Cubic centimetres of water added to iodine.	Cubic centimetres of I taken.	Cubic centimetres of thiosulphate.	Cubic centimetres of I used (total).	$\text{SO}_2$ per cent.	$\text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O}$ per cent.	Initial of observer.

It should be mentioned that the observers worked with different balances, weights, burettes, and normal solutions, and in different laboratories. In the above experiments in no case was  $\text{HCl}$  used to liberate the  $\text{SO}_2$  before titrating, it being assumed that the  $\text{SO}_2$  would have a greater tendency to oxidise when in the free state than when combined. The following series of experiments in the presence of  $\text{HCl}$ , as recommended by Fresenius, hardly confirmed this opinion, but it will be seen that the results were very irregular, and that the use of this acid is not to be advised. (Table 5.) It should be mentioned that in the trials the sulphite was dissolved in the stated quantities of acid and water, and then immediately poured

into excess of iodine. The aeration of the water therefore accounts in some measure for the low results.

TABLE 5.

The authors observed some years ago that when sulphite of sodium was titrated with normal acid, using cochineal as the indicator, the end point occurred when the following reaction was complete:—

the pink colour of the cochineal not being changed to yellow in the presence of  $\text{Na}_2\text{SO}_3$  until the latter is entirely converted into bisulphite—that is, while the normal sulphite reacts strongly alkaline to cochineal, the bisulphite is neutral, and free sulphurous acid is strongly acid to this indicator. The remarks of Mr. Thomson upon the action of acids upon the sulphites of sodium confirmed the authors' previous observations, while the indicator employed by him (methyl-orange) is decidedly more delicate. The following results were obtained by titrating the same sulphite as before used with  $\frac{n}{2}$  acid. In one set methyl-orange was used, in the other cochineal tincture.

TABLE 6.

Sulphite used, Grammes.	Cubic centimetres of water used.	Cubic centimetres of $\frac{n}{2}$ acid used.	$\text{Na}_2\text{SO}_3 \cdot 7\text{H}_2\text{O}$ Per cent.	Indicator used.
2.5	100.0	19.8	99.76	M. Orange
2.0	100.0	15.75	99.22	M. Orange
2.0	100.0	15.7	98.91	Cochineal
2.0	100.0	15.7	98.91	Cochineal
2.0	200.0	15.7	98.91	M. Orange
2.0	200.0	15.65	98.59	Cochineal
2.0	500.0	15.40	97.02	M. Orange
1.0	250.0	7.7	97.02	Cochineal

The influence of the dissolved oxygen is thus as clearly established in the above trials as when iodine was used under like conditions of dilution. In both cases the percentage of sulphite rapidly diminishes with the increased volume of water employed.

## SUMMARY.

The method of procedure recommended by the authors for the general estimation of sulphurous acid in its compounds may be briefly summed up as follows: The sulphite, if solid, is weighed out on a watch glass,

and introduced at once *without dissolving it in water* into a known *excess* of decinormal iodine; after stirring till the reaction is complete, which takes some little time when insoluble sulphites (*e.g.*, calcium sulphite) are dealt with, the excess of iodine is determined in the usual way by means of decinormal thiosulphate and starch; a second experiment is then

made, in which a *slight* excess only of the  $\frac{n}{10}$  I, as indicated by the first trial, is employed, and the titration carried out as before. The writers in the foregoing remarks have only instanced the sodium salt, but they have found the method equally accurate for the estimation of concentrated sulphurous acid solution and bisulphites, the reverse action of  $\text{SO}_2$  upon hydriodic acid noticed by Bunsen not affecting the result. The following compounds of  $\text{SO}_2$  have been repeatedly analysed in the foregoing way, and have given highly concordant results with those obtained by the much more tedious gravimetric method: Solution of  $\text{SO}_2$ , specific gravity 1.067 at  $11^\circ \text{C}$ ., containing 13.1 per cent. of  $\text{SO}_2$ ; bisulphites of sodium (solid),

hours or more. By simply tightening the small screw more or less, any desired flow of gas can be obtained and regulated, and one of these siphons will evolve about 500 litres of  $\text{SO}_2$  gas.

#### DISCUSSION.

DR. ARMSTRONG said it was extremely desirable to have not only simple but accurate methods of analysis. This method of Messrs. Giles and Shearer had both these merits, as he could say from comparative tests in his laboratory, in which the results were concordant and accurate. With regard to the siphon of sulphurous anhydride he found it extremely handy and of especial value where many iron determinations had to be made.

MR. B. E. R. NEWLANDS regarded the siphon arrangement for sulphurous acid gas as a valuable adjunct in the laboratory, having employed it for some time. With regard to the authors' method, he was of opinion it was more especially useful where numerous estimations had to be rapidly made. For ordinary and occasional work the old method of ox-

potassium, ammonium, calcium, magnesium, zinc, etc., some of these bodies containing over 60 per cent. of  $\text{SO}_2$ ; the sulphites of sodium, ammonium, calcium, magnesium, aluminium, zinc, etc. In the case of fluids, the solutions are sealed up in small, thin blown glass bulbs, and broken under the iodine when loss of gas is apprehended. The solutions are previously cooled in a freezing mixture. The writers, in conclusion, throw out the suggestion that the very rapid absorption of oxygen in water by normal sulphite of sodium may be worthy of attention as a means of determining dissolved oxygen in water analysis. They have also pleasure in bringing to the notice of the Section the very convenient form in which anhydrous sulphurous acid liquefied is now offered by Messrs. A. Boake and Company. The small apparatus shown at work has been of great service to them in their investigations, as it is capable of affording a steady stream of pure  $\text{SO}_2$  gas for forty

hours or more. By simply tightening the small screw more or less, any desired flow of gas can be obtained and regulated, and one of these siphons will evolve about 500 litres of  $\text{SO}_2$  gas.

THE CHAIRMAN congratulated the authors on the very thorough way in which they had investigated the difficulties of analysis of sulphites. It was a subject of increasing importance now that sulphurous compounds are so extensively employed. The example of publication of laboratory notes in this form was one which he trusted might be followed by many members, and he ventured to think it could be done without prejudice to private interest.

#### FURTHER NOTES UPON THE SOLIDIFICATION OF LIQUID FATTY OILS.

BY WM. LANT CARPENTER, B.A., B.SC., F.C.S.

AT the meeting of this Section, in March, 1883, I gave a somewhat detailed account, which appeared in the

Journal of the Society for March 29th of that year, of the ingenious process of M. St. Cyr Radisson, of Marseilles, for converting liquid oleic acid (the chief residue in the manufacture of stearic and palmitic acid from neutral fats, such as tallow, palm oil, etc.) into solid crystalline palmitic acid. The process is founded on the laboratory reaction announced in 1841 by Varentrapp, that when oleic acid was heated with a great excess of caustic potash it was resolved into palmitic acid, acetic acid, and hydrogen, or

Regarded from the point of view of this Society the process may be shortly described as that of a fusion with excess of caustic alkali at a high temperature, and it is in the practical carrying out on a large scale of this difficult laboratory operation that the special interest of the process consists.

In the discussion which followed my paper I was asked some questions of detail as regards the apparatus employed, which I was then unable to answer; but having in August last spent several days in Marseilles with the inventor, I propose now to give a little further information on the subject. The process was patented in most European countries, and in the United States, the English patent being June 9th, 1869, No. 1782, and the American, April 12th, 1870, No. 101935; but a variety of causes have prevented M. Radisson from making known his invention as widely as it deserves. The vessel in which the fusion takes place is technically called a "cartouche," and is shown in section in the annexed figure. It is a cylindrical vessel A B, 3·20 metres in diameter and 1·30 metre in height, the two ends being slightly dished, and the bottom made of cast iron, while the sides are of wrought iron. The whole is set in brickwork in such a way that the bottom is at least 1·75 metre above the fire-bars M, thus giving a large fire-chamber, a very important point in the facility for control of temperature and maintenance of a uniform heat. The cartouche contains any convenient mechanical agitator C, worked with gearing D, also a manhole E, safety valve at F, steam and water cocks G, H, exit pipe J, for steam and hydrogen, and a large outlet pipe K, with suitable valve for removing the fused mass at the end of the operation. In working with caustic potash, the original form of the process, the cartouche is charged with 1,500 kilos. of oleic acid and 2,500 kilos. of caustic potash ley of specific gravity 1·400. Heat is applied, and when the disengagement of steam ceases, the manhole E is closed, and the evolved gases pass through J to a coke-tower condenser, and thence to a gasometer or gasholder. At 290° C. decomposition commences and much hydrogen is evolved. From 300° to 310° C. is the proper temperature for the operation, and at 320° the odour of the evolved gas changes, and the operation is then suddenly arrested by injection of steam into the mass, by the Giffard injector I, in order to avoid destructive distillation. From 36 to 40 hours are required for one complete operation in the cartouche, including filling and emptying. The progress of the operation is judged by taking samples, which are decomposed, and tested for the melting point of their fatty acids. The method employed is that of Dalican, universally adopted in France, which gives really the "point de figeaison," or congealing point of the fatty acid, within 0·1° or 0·2° C.

Writing in 1878 a short account of his enormous candle factory and of the objects exhibited for the Industrial and International Exhibition in Paris, M. Fournier says of this process, "La maison exploite depuis trois ans le système Radisson dans une annexe de son usine, et chaque jour elle transforme 2 à 3000 kilogrammes d'acide oléique en acide palmitique. La stéarinerie a donc pris possession d'une manière

définitive de ce nouveau procédé si important pour son avenir. Cette transformation est la nouveauté

### CORRECTION.

BRISTOL WATER.—In his paper "On the Filtration of Potable Water," which was published in the March number of the Journal, Mr. S. H. Johnson includes Bristol among the towns which "are still supplied with sewage-contaminated water from rivers and surface wells." We are informed that the water supplied by the Bristol Waterworks Company is not supplied from sewage-contaminated sources, but "from copious springs on the north side of the Mendips, and from a well at Chelvey, from which places the water is conveyed in culverts and pipes the whole distance, and is therefore entirely free from surface contamination."

The next meeting of this Section will be held on Wednesday evening, 7th May, 1884.

UNIVERSITY COLLEGE, ASHTON STREET, LIVERPOOL,

April 2nd, 1884.

PROP. J. CAMPBELL BROWN IN THE CHAIR.

## INJURY DONE TO VEGETATION BY GASES ARISING FROM CERTAIN MANUFACTURING PROCESSES.

BY SIEGFRIED HAMBURGER, PH.D.

THE question of damage done to vegetation by smoke and acid gases escaping from the chimneys of manufacturing establishments is comparatively of recent date, and complaints seem to have increased with the progress which industry has made in the last decades. Such complaints have principally been brought forward in districts where many manufactures were carried on, and the blame was always laid at the doors of chemical manufacturers, and especially the alkali makers, of whose works it was known that they gave rise to large quantities of acid gases. Lately this subject has been taken up by several unprejudiced investigators, and great credit is due to them for having shown that gases arising from other manufactures may be equally noxious, and even more so. Much, however, still remains to be done in that direction. People somehow cling to their old belief, and every endeavour ought to be made to dispel that erroneous notion. That is the object of this paper. I shall give you the results of analyses and experiments I have made, and the conclusions I have drawn from them. But I wish to remark here that the samples of leaves, grasses, etc., used for my purpose were collected in a somewhat casual way while I was taking a walk, and without a view to the publication of the results of my investigation. Thanks are also due to several friends of mine who have sent me specimens of leaves from different parts of this country.

Some time ago Mr. R. Hasenclever, of Aachen, the well-known director of the Rhenania Alkali Company, published in the German *Chemische Industrie*\*, an excellent paper on the same subject, and I shall give you some of his statements. Dr. Angus Smith, who is perhaps the greatest living authority on chemical climatology, treats this matter in his well-known book on "Air and Rain," and I have taken some quotations from that work.

At the outset permit me to state in what way my analyses and tests were carried out. On seeing in a field, or on trees, grasses or leaves whose appearance seemed to indicate that they had been attacked by noxious vapours, I tried their surface for the reaction upon damp litmus paper, and tested them afterwards in the laboratory for  $\text{SO}_3$  and Cl. Sometimes I analysed plants which were looking healthy, but were growing in the immediate neighbourhood of suspicious specimens, so as to compare the results. Only four times out of several hundreds of tests with litmus paper did I find a distinct acid reaction. We shall see later on that tests with litmus paper are misleading. The analysis was conducted by saturating the weighed substance with a weak solution of pure  $\text{Na}_2\text{CO}_3$ , boiling down to dryness, and incinerating the residue in a platinum crucible. The ash was lixiviated with water, and the filtered solution divided into two equal parts, in one of which  $\text{SO}_3$  was determined,

and in the other Cl was estimated. On other occasions I lixiviated the substance with a weak solution of  $\text{Na}_2\text{CO}_3$ , filtered and evaporated to a smaller bulk. After dividing the extract into two equal parts, I tested one for  $\text{SO}_3$ , and the other for Cl in the usual way. The leaves were then dried and incinerated in a crucible, adding some  $\text{CO}_3\text{Na}_2$ . The ash was treated as mentioned above.  $\text{SO}_3$  and Cl are given in the table below, as well as ashes, all calculated for 100 parts of the dry substance of the plants. I should just like to mention that the St. Helens specimens, from 1 to 13, were taken from a part of the neighbourhood which is most frequently exposed to the smoke of alkali works.

Now you will at once observe that even in the same localities the amount of  $\text{SO}_3$  and Cl is very variable. Furthermore, while the leaves of one plant, with a considerable amount of both constituents, gave an acid reaction, those of another, with the same amount and sometimes even more, gave a neutral reaction, showing clearly that the presence of free acid is no proof that the organism of the plant is saturated with acid. It seems very strange, and it does not allow of easy explanation, that a plant with so large quantities of  $\text{SO}_3$  and HCl can show a neutral reaction, provided that these acids were originally deposited in an uncombined state. However, this must not be the case. Indeed, we have much reason to suppose that the Cl was deposited on the plant combined with Na as NaCl, but the same cannot be said of the  $\text{SO}_3$ . As there are only traces of ammonia present in the extract of leaves, it is difficult to see what strong basic compounds have acted upon  $\text{SO}_3$  so as to rob it of its acid nature. In "alkali towns" we may perhaps assume that alkaline matters are present in the air, which have been mechanically carried away from the black ash chimneys. But this explanation will not hold for such towns as Derby, for instance (*vide Anal.* 20 and 21). Objections might be raised that my analyses do not represent a fair average of specimens, as they are taken in fine weather. But I really do not think it matters much, as any free acid, accumulated by condensation, etc., etc., would be washed down into the earth by subsequent rain, and thus escape detection. Besides, the analyses go to show that a small amount of free acid does no harm to the plant which absorbs it in a way still unknown to us. The same will, perhaps, also explain why I did not find as much Cl as we should have expected. I leave the question open, and would be glad to hear the opinion of members on this point.

Mr. Hasenclever, in giving the results of some twenty analyses of leaves taken from trees from different localities, unfortunately does not state the reaction of the leaves which he submitted to analysis, nor the appearance and health of the trees from which the samples were taken. This omission is all the more regrettable, as the outward appearance, when properly interpreted, gives most important indications in our present imperfect state of knowledge of this subject.\*

\* Since writing this paper Mr. Hasenclever has been kind enough to inform me of the reason why he did not state the reaction of the leaves or the watery extract respectively. He says: "According to my experience, and to the investigations of Prof. Freytag, of Bonn, and Prof. von Schroeder, of Tharand, we are not entitled to draw the conclusion that a plant must be saturated with free acid because it has an acid reaction on its surface." I certainly agree with him in that, and I have already taken an opportunity of pointing this out in the remarks following the results of my analyses. But I thought it important to give the reaction of leaves, just in order to show that in leaves with an acid reaction the quantity of  $\text{SO}_3$  and Cl may be smaller than in those with a neutral reaction. Like other investigators, I did not think it necessary to make a separate determination of the free acid. Mr. H.'s arguments on this point well deserve attention. He proceeds to say that in a lawsuit for damage done by the smoke, the following technical evidence was given: "The estimation of

To return to my analyses. You will also see that on the whole the amount of  $\text{SO}_2$  exceeds that of  $\text{Cl}$ , in some cases even considerably. It would be wrong to assume that all  $\text{Cl}$  found in the plants was originally present as  $\text{HCl}$ . It is well known that our ordinary fuel, coal, contains  $\text{Cl}$  as  $\text{NaCl}$ , but there is no  $\text{Cl}$  to be found in coal-ash, and it is only reasonable to infer that the  $\text{NaCl}$  has been driven out with the other volatile constituents. It has also been proved that in non-manufacturing districts,  $\text{NaCl}$  has been found in the rain, undoubtedly produced by coal burnt in household fires. In industrial districts this will be all the more the case. In some instances, as previously indicated, the presence of  $\text{NaCl}$  may be accounted for by the fact that some alkali makers allow the escape of their  $\text{HCl}$  condensers to go into the black-ash chimneys, which mostly have an alkaline reaction.

We will now consider the  $\text{SO}_2$ . The amount of this gas escaping from alkali works or their O.V. plant respectively is so small as certainly not to be in proportion to that found in different plants. The  $\text{SO}_2$  must therefore be generated in another way, and in the case of St. Helens I have only to allude to such industries as glass works and copper works. But a far larger amount is produced by the consumption of coal as fuel. I may safely say that the coal used in works for firing contains on an average 2 per cent. of volatile sulphur—as a rule as pyrites, “coal brasses”—which on burning give off  $\text{SO}_2$ . To give you an idea of the amount usually present in the air, I quote the figures of Dr. Angus Smith, who calculates that in a part of London, where coal is only consumed for domestic purposes, a million cubic feet of air contains 730 grains of  $\text{SO}_2$ . At Manchester, where coal is largely consumed for industrial purposes, the figure rises to 1,098 grains of  $\text{SO}_2$ . I found at St. Helens, as an average of several determinations, 1,260 grains of  $\text{SO}_2$  in one million cubic feet of air. Mr. Fletcher calculates (in 1879) as gases escaping into the air of St. Helens *per week* :—

From fire gases.....	800 tons $\text{SO}_2$
From copper works.....	380 tons $\text{SO}_2$
From glass works.....	180 tons $\text{SO}_2$
From alkali works.....	25 tons $\text{HCl}$

That is to say, the alkali makers turn out less than one-seventh of the amount of the glass works and less than one-fifteenth of that of the copper works. I have calculated\* to what figure the percentage of fire gases for  $\text{SO}_2$  may rise, if we burn coal of the following average composition :—

	Per cent.
Carbon.....	67.4
Hydrogen.....	4.1
Oxygen.....	6.6
Nitrogen.....	1.2
Water.....	2.0
Volatile Sulphur.....	2.0
Ash, etc.....	16.7

Suppose we burn such a coal with just the necessary

free acid in the extract of leaves does not warrant the conclusion that the leaves contained free acid. Aqueous extracts of plants quickly undergo decomposition, giving rise to the formation of organic acids. The extract of beech and oak leaves examined for free acid showed, that the extract of beech leaves from the Kettendorf (a neighbourhood free from smoke of chemical works), contained as much free acid as that of the leaves of the same kind of tree from the “Kleine Probststet” (in the neighbourhood of chemical works). The same was the case with oak leaves.” Prof. von Schroeder and Carl Reuss say in their exhaustive book on “Damage Done to Vegetation by Smoke”: “The extraction of leaves with water is a clumsy process: it can never be uniform or complete. The  $\text{CO}_2$  interferes with the method, and the extract undergoes decomposition even at ordinary temperatures, and at the boiling point, quickly enough to allow alterations to go on in the percentage of free organic acids. To prove injury done by smoke the determination of free acid by itself is worthless in every case. Still more faulty are those statements, often used in evidence, that the injured plants gave a very strong acid reaction with litmus paper.”

\* *Industrie-Gase* v. Dr. Clemens Winkler.

quantity of air, avoiding any excess whatever, then 100lb. of coal will change as follows :—

67.4lb. C require	179.7lb. O and yield	247.1lb. $\text{CO}_2$ .
4.1lb. H require	32.3lb. O and yield	36.9lb. Steam.
1.2lb. N.....	yield	1.2lb. N.
2.0lb. $\text{H}_2\text{O}$ .....	yield	2.0lb. Steam.
2.0lb. S.....	yield	4.0lb. $\text{SO}_2$ .

100.0lb. of coal require 211.5lb. O and yield 291.2lb. fire-gases.

We have now to deduct 6.6lb. O found in the coal from 211.5lb. O required, and we have to take from the air  $211.5 - 6.6 = 204.9$  lb. O, where we find it mixed with

$$\frac{207.9 \times 76.8}{23.2} = 688.2 \text{ lb. N}$$

which increases the amount of fire gases to  $291.2 + 688.2 = 979.4$  lb., consisting of—

	Vol. in cub. ft. 0° C. and 760mm. B.
247.1lb. $\text{CO}_2$ .....	2008.4
36.9lb. Steam.....	733.4
1.2lb. N.....	15.3
2.0lb. Steam.....	39.7
4.0lb. $\text{SO}_2$ .....	22.4
688.2lb. N.....	8791.6
	11610.8

The fire gases would therefore contain—

$$\frac{22.4 \times 100}{11610.8} = 1.93 \text{ vol. per cent. of } \text{SO}_2$$

However, in burning on the large scale, we have to dilute the gases with an excess of air, in order to bring about complete combustion. Further, when they reach the atmosphere at the top of the chimney, they at once mingle with air, by which a considerable dilution takes place. Notwithstanding all that, we must not forget that the classical investigations of Professor Freytag, have proved, that air containing more than .003 volume per cent. of  $\text{SO}_2$  will do injury to vegetation. That would mean to bring down undiluted fire gases to such a low percentage of  $\text{SO}_2$ , they must be mixed with 64 times their own volume of air, and I do not believe that we can reach that degree of dilution in crowded manufacturing districts, *when the atmosphere is in a moist state*. Besides, cold and rain, etc., produce condensation—that is, concentration of the acids, and at such times the vegetation must be affected. We can therefore conclude that it is not  $\text{HCl}$  which does the damage, but  $\text{SO}_2$  produced by coal burning, etc., and the analyses 20 + 21 in my table, compared with No. 22, support this point of view. I shall give you another striking illustration of my assertion just made in two examples, mentioned by Professor Stoekhardt, in the *Tharander Forstliches Jahrbuch*.† In a farmyard, there were near the chimney belonging to a boiler fire two chestnut trees, which had been able to withstand for several decades the smoke of oak-wood serving for fuel. After changing the fuel from wood to coal, the trees commenced at once to show signs of decay and died in the second year, the young leaves getting killed soon after they appeared. At another place an orchard was completely destroyed, when a brick furnace which had been supplied with wood for 20 years was rebuilt and arranged for coal firing. I could add a good many more examples, which would only serve to prove the same, namely, that the carrying on of large industries, or more accurately the consumption of much coal in a small district, is incompatible with a flourishing vegetation. Mr. Hasenclever and certain public bodies who have carefully inquired into the question of injury to vegetation have come to this conclusion. They admit that damage is done—in fact, nobody can deny it—but

\* It seems rather strange to speak of steam at 0° C., but it makes no difference in the result whether we assume the gases at 0° C. or 150° C., or any other temperature.

† *Thar. Forstl. Jahrbuch*, Vol. 21, page 31.

No.	Specimen taken at	Kind of Plant.	Reaction of Leaves.	Per 100 Dry Substance.			Remarks on Appearance, etc.
				SO <sub>2</sub>	Cl	Ash.	
1	St. Helens (after some days of damp weather)	oats	slightly acid	2.89	.80	11.31	bad crop; yellow corrosions on edges.
2	St. Helens (after some days of fine weather)	grass	neutral	2.21	.69	10.37	discoloured.
3	St. Helens (about 1 mile off alkali works, Parr)	clover	neutral	2.56	1.13	9.38	fair crop; leaves good.
4	St. Helens	grass	strongly acid	2.09	1.24	11.29	corroded over the whole surface.
5	St. Helens	potatoes	neutral	2.53	1.16	9.06	good crop; leaves had no marks.
6	St. Helens (about 1 1/2 mile off alkali works, Laffak)	apple tree	slightly acid	1.49	.65	9.40	yellowish-red corrosions; tree nearly destroyed.
7	St. Helens	apple tree	neutral	1.86	.61	10.22	good; few marks on leaves; corrosions.
8	St. Helens	potatoes	strongly acid	3.26	.82	9.09	good crop; leaves brown corrosions?
9	St. Helens	potatoes	neutral	2.89	1.12	9.35	good crop; leaves had no marks.
10	St. Helens (about 2 miles off alkali works, Garswood, bc.)	turnips	neutral	2.56	1.01	10.30	leaves corroded.
11	St. Helens (between Wigan and St. Helens)	hedges	neutral	1.09	1.02	11.39	yellow-brown corrosions; decaying.
12	St. Helens	beech	neutral	2.19	1.33	10.94	yellow-red corrosions.
13	St. Helens	beech	neutral	1.36	2.04	11.36	tree higher than the surrounding ones; top destroyed, probably owing to exposure to wind and weather; leaves had no marks.
14	St. Helens—St. Ann's	rhododendron	neutral	1.60	1.59	7.01	leaves discoloured and much corroded, nevertheless the plant was flowering very well.
15	St. Helens—Windlehurst	holly	neutral	2.01	.30	8.61	good.
16	St. Helens—Crank	elm	neutral	2.40	1.06	11.21	yellow-brown corrosions, tree decaying. It was standing by itself, without any shelter whatever.
17	St. Helens—Moss Bank	hedges	neutral	2.86	1.47	11.42	good.
18	Prescot	oak	neutral	.81	.19	8.38	
19	Prescot (Knowsley Park)	elm	neutral	1.16	.31	11.14	leaves much corroded; tree decaying; the top already destroyed.
20	Derby (part of the town exposed to smoke of works)	poplar	neutral	1.09	.29	12.71	
21	Derby	apple tree	neutral	1.63	.39	8.22	tree decaying.
22	Derby—no works	poplar	neutral	.76	.09	11.08	good.
23	Neighbourhood of London—no works	shrubs	neutral	.98	.21	13.61	
24	Liverpool—Sefton Park	holly	neutral	1.12	.20	7.38	

the question of remedy is a most difficult one, and it is not easy to approach it without interfering with the natural development of industry. For this reason I cannot agree with those who suggest opposition to the accumulation of works in one place or district, as experience goes to show that smoke does no harm to vegetation if in proportionally small quantities. The technical means which have been devised to prevent or at least to lessen the damage have not been successful up to the present. It is not sufficient to insist upon chimneys being built high in crowded industrial districts. They do not dilute the gases enough in damp weather, especially if the quantity is very large, as is always the case in manufacturing towns. They may do very well for isolated establishments. The washing of smoke is still in its infancy, and we have to overcome a great many mechanical difficulties before we can consider that matter seriously. If we ever solve the problem of condensing diluted acid gases, then we may confidently hope to remove the greatest enemy of vegetation— $\text{SO}_2$ . That manufacturers are not opposed to condensation, as is often asserted, is best proved by the example which the alkali-makers have given to the public. They certainly deserve to be complimented on the manner in which they have brought to perfection the condensation of  $\text{HCl}$ . In spite of many most expensive failures, they continued their experiments till they succeeded, and it is therefore neither fair nor reasonable to harass them with unfounded accusations.

Besides acid gases, there are a good many other causes of the decay of trees, such as exposure to wind and weather, drainage of the forest, or the removal of fallen leaves. But as these do not concern our subject, I am satisfied with only mentioning them. However, one ought to ascertain whether those reasons were not the immediate cause before hastily forming the conclusion that the damage had been done by noxious gases.

All plants do not suffer in the same degree from acid gas; fruit-trees are most sensitive to it, while forest trees have a stronger constitution. Agricultural plants show a still more powerful resistance. Those who take an interest in this matter will find a table, indicating the 'scale of injury,' at the end of Dr. Angus Smith's book on "Air and Rain." Some people contend that the soot in the smoke may damage vegetation by choking up the pores of plants, but Prof. Stoeckhardt has proved by direct experiments that this is not the case, even if the quantity of soot is so great as to give the tree a coal-black appearance. All other conditions being favourable, the tree continues growing, as if nothing had taken place.

I shall now give you the result of some experiments which I made, in order to find out what amount of  $\text{SO}_3$  and  $\text{HCl}$  a certain kind of a plant can take up without suffering from corrosions, and what reaction within the plant brings about its decay. I exposed

leaves to the action of  $\frac{n}{10}$ ,  $\frac{n}{100}$ ,  $\frac{n}{1000}$ , and  $\frac{n}{2000}$   $\text{SO}_4\text{H}_2$  and  $\text{HCl}$  of equivalent strength. The normal acids produced discolouration in less than half an hour, yellow-brown spots appearing in the middle of the leaves, and extending gradually over the whole surface. The  $\frac{n}{10}$  was also too strong, although it took about three hours before the first signs of destruction appeared; the  $\frac{n}{100}$  acid acted in about a day, but already here the action of  $\text{SO}_4\text{H}_2$  was stronger than that of  $\text{HCl}$ . The  $\frac{n}{1000}$   $\text{SO}_4\text{H}_2$  produced discolouration in about a week. The  $\text{HCl}$  of

equivalent strength required 10 days. An  $\frac{n}{2000}$  acid ('0245 grm.  $\text{SO}_4\text{H}_2$  and '01825 grm.  $\text{HCl}$  per litre) seems to have no action. Two green-house plants were submitted to a daily spray of the  $\frac{n}{2000}$  acids, and showed no corrosion after one month. With different specimens time and concentration of the acids will probably have other consequences. But having not sufficient time at my disposal I had to discontinue these observations.

With regard to the reaction which is going on within the plant, I prepared an alcoholic solution of chlorophyll by digesting green leaves with absolute alcohol. The solution retains its green colour for a long time when kept in a stoppered bottle, but changes to a dirty-brown, and gradually deposits a brown precipitate, when an acid acts upon it. This takes place at once with an acid of moderate strength, but with a very dilute acid it requires some time. On the surface of corroded leaves we meet with a similar discolouration, and if we adopt the theory that it is the chlorophyll which decomposes the carbonic acid, we can well understand that a plant must die if the destruction of the chlorophyll has extended over a considerable part of the leaves. The corrosion of leaves brought about by acid gases can be compared with an inflammation of the lungs in the human body.

Let us now look at the value we may give the results of chemical analysis. Dr. Angus Smith holds "that in many cases we might be able to show by analysis that acid gas has been the cause of injury," but I can find no analyses in his publications which support his opinion. I cannot quite agree with him, because I found the same amount of  $\text{SO}_3$  and  $\text{Cl}$ , and even more in healthy plants than in decaying ones (*vide Anal.* 6 and 7). Mr. Koenig\* has had the same experience, and found more  $\text{SO}_3$  in a healthy-looking larch tree than in a diseased one. I think a different state of the atmosphere exercises a different action, other things remaining the same. We may perhaps be able to prove conclusively injury caused by a certain gas from a particular works, if we happen to catch the right moment, which is exceedingly difficult. The utmost precaution is necessary before pronouncing a decisive opinion. Nevertheless, if we continue to study this matter, we shall obtain valuable information, and for this reason I wish to give some indications to chemists who may be called upon to investigate in such cases. One commences by collecting in the immediate neighbourhood of the district in which complaints arise suspicious specimens as well as healthy ones, which are then to be compared chemically with each other. The outward appearance alone is no criterion for injury done by gas, as I often saw marks on the surface of leaves which had been caused by fungi and insects in an undeveloped state, and which were just like marks from acid corrosion. It would be advisable to examine all specimens by the microscope. Plants from other parts of the country, under the same climatic conditions, may also serve for comparison. Besides, the "scale of injury" is a very important indicator; and if, for instance, fruit-trees are less damaged than forest-trees or corn, it is very improbable that the injury was done by smoke. However, one must notice whether the fruit-trees had not some sort of shelter which kept off the gases, as practical farmers have often observed, especially with corn, that seemingly unimportant causes, such as a small elevation, hedges, etc., were able to protect their property from the influence of noxious gases. Further, we would have to test the air and

rain for acidity, making allowance for climatical changes; and better still, wherever possible, to make direct experiments with gases under the same conditions as complained of, and observe the reactions. The chemical investigation will chiefly consist of estimating  $\text{SO}_3$  (I never found  $\text{SO}_2$  in the extract) and Cl. Other requirements for special cases will suggest themselves to the investigator, and I should be pleased, if other gentlemen would take up this matter and publish their results for the benefit of the much harassed chemical manufacturers. The literature on this subject is very poor indeed, and more information is badly wanted. I shall myself continue my observations, and may have an opportunity of giving you further results at some future date.

I conclude with the words of Mr. Hasenclever: "The blame for injury done to vegetation can be brought home more or less to all manufacturing establishments; but one must not forget that this is only a small nuisance compared with the great economic advantages mankind owes to the enterprising spirit of industry. A great improvement has already taken place, and Dr. Angus Smith, in speaking of the former and the present state of things, considers them as different as barbarism and civilisation."

Owing to the late hour the discussion was postponed until the next meeting.

## ON THE OXIDATION OF CELLULOSE, WITH SPECIAL REFERENCE TO THE CHEMISTRY OF BLEACHING AND PRINTING.

BY C. F. CROSS AND E. J. BEVAN.

THE chemical activity of cellulose, in those forms best known to the technologist, is not of a pronounced character—indeed, it may be defined as an inert substance. Were it not for this absence of affinity, which is a distinguishing characteristic of cellulose, it could not play the important part which it does in the chemical laboratory. As it is, however, cellulose is the almost universal medium of separation by way of filtration, and in point of usefulness stands, perhaps, only second to water. This important function of

cellulose is obviously conditioned by its inability to enter into stable combination with the acids, bases, and salts with which inorganic analysis has to do. On the other hand, it is a matter of experience that there does exist in cellulose a certain power of attraction for these compounds, and this attraction is considered by certain investigators to be of a truly chemical nature, i.e., to result from the structure of the cellulose molecule itself. Thus Mills and Takamine have shown (*Chem. Soc. Journ.*, 1883, 153) that cotton, when immersed in dilute solutions of hydric chloride and of sodium hydrate, concentrates these compounds within itself to an appreciable extent, the ratio in which they are respectively attracted being of a simple molecular character, viz.,  $3\text{HCl} : 10\text{NaOH}$ . It is also worthy of notice that the ratio determined for silk was the same, whereas for wool it is  $2\text{HCl} : 3\text{NaOH}$ . This attraction, however, is of so feeble a character that it is overcome by water, and when it is considered that the ultimate visible structure of these fibres must play some part in the result, it is difficult to say to what extent it is not due to mere osmotic differentiation. On the other hand, it is not for us to imagine, still less to assign, a mutual limit to the action of the so-called chemical and physical forces. Rather we would join in the anticipation that the investigation of bodies like cellulose may contribute to the breaking down of the barrier erected by classification, in showing that osmose is a truly molecular phenomenon.

Passing from the laboratory to the factory, experience of the numerous applications of cellulose, notably in the textile arts, teaches us that it has an activity which can be evoked under suitable treatment, and it is to certain operations of the bleacher and colourist that we wish to direct attention from a point of view that has hitherto been conspicuously neglected. Some time since, with the view of throwing light upon the constitution of cellulose, we made a study of its oxidation by nitric acid. Purified cotton was boiled with the strong acid (50 per cent.) for several hours, and the solution, containing a large quantity of oxalic acid, was filtered from the insoluble residue. This amounted to about 30 per cent. of the weight of the original cotton, and took the form of a fine white powder, which, however, on washing, was converted into a gelatinous mass. In this form it was entirely soluble in dilute alkalis, and was precipitated from such solutions in a form resembling pectic acid on the addition of acids, alcohol, or saline solutions. This substance, which we provisionally termed oxycellulose, was prepared by similar treatment from jute cellulose and also from the pith of *Aralia papyrifera*. The products obtained from these several sources we proved to have the same composition, viz.,  $\text{C}_{18}\text{H}_{26}\text{O}_{16}$ , differing from cellulose by  $-\text{H}_4 + \text{O}$ . This derivative resembles in many of its properties the original cellulose. Thus, when dissolved in concentrated sulphuric acid it is converted into a gummy substance, dextro-rotatory, and otherwise resembling ordinary dextrine. Treated with a mixture of nitric and sulphuric acid it is converted into the nitrated compound  $\text{C}_{18}\text{H}_{23}\text{O}_{16}3(\text{NO}_2)$ . The important feature of this decomposition of cellulose by nitric acid is undoubtedly the residual oxycellulose which we have just described, and the retention by this of the main chemical features of the original cellulose molecule, from which, as we have seen, it differs chiefly in manifesting feebly acid properties, and a considerable capacity for hydration (gelatinisation). At the same time that we examined this oxycellulose, produced in the laboratory, we noticed in our examination of certain natural fibres, the results of which we published in conjunction with Mr. Webster (*Chem. Soc. Jour.*, Jan., 1883), that some of these appeared to contain similar

products of the oxidation of cellulose. We also observed that these manifested a strong attraction for certain colouring matters, considerably in excess of that shown by lignified fibres under the same conditions, whereas, in the regard to the majority of colouring matters, the dyeing capacity of these latter fibres is much greater. We, in fact, proposed, on the basis of these results, a dyeing test of the presence of oxidised derivatives of cellulose. Almost simultaneously with the publication of these results there appeared in the *Journal of the Société Industrielle de Rouen*, a remarkable paper by M. G. Witz, a vice-president of that society, detailing the results of an exhaustive study of the oxidation of cellulose (cotton) by solutions of bleaching powder—from a point of view, therefore, of peculiar interest to technologists. We have recently had an opportunity of visiting M. Witz, and we have been so impressed with the importance of his researches, in their practical as well as theoretical bearings, that we think it desirable to lay before the Society an account of their main results, referring those who desire a more complete knowledge to the original papers in the *Bull. Soc. Ind. Rouen*, [10], 5, 416, and [11], 2, 169; also to *Dingl. Polyt. Jour.* 250, 271.

The bleaching operations in the works with which M. Witz is connected, came, a few years since, under suspicion, in consequence of a certain proportion of the finished pieces presenting the appearance of being riddled with a number of minute holes. On making specimen dyeings of these pieces with certain aniline colours it was found that the holes were picked out as dark spots upon a light ground, the result being due to a powerful attraction of the colour at the margin of the holes. It was then found that a result precisely similar was obtained by throwing a fine dust of bleaching powder upon ordinary bleached calico, previously wetted, and allowing it to stand some time, then washing off and dyeing. In this way the spoiling of the goods was traced to the injudicious manipulation of bleaching powder in the neighbourhood of the washing tanks. The cause of the accident was removed, but not until it had served the end of science in opening up a field for investigation. The next extension of these preliminary results was to throw light upon the cause of the familiar occurrence of brown patches in the whites of printed goods, the development of the brown colour always taking place during the steaming of the goods, and being accompanied by a "tendering" of the cloth. This effect it had been usual to ascribe to defective bleaching. It was now, however, found that the behaviour of the brown patches towards the aniline colours and other reagents was similar to that of cloth which had been oxidised by bleaching powder in the manner described above. It had also long been known that these patches were never visible till after the steaming. From these materials a deductive investigation was proposed, the result of which was to prove beyond doubt that the phenomenon was one not of deficient but of over oxidation. The immediate cause was then not far to seek. It lies in those circumstances which bring about an unequal action of the bleaching solution. The more prominent of these we will briefly elucidate.

1. *Action of the Air*.—To demonstrate the joint action of air and a solution of bleaching powder upon cotton M. Witz suspends vertically a strip of dry bleached calico about eight inches in length, with its lower end immersed to the distance of one inch in a solution of 4° B. At the expiration of one hour it is washed off and dyed in methylene blue—a solution of  $\frac{1}{2000}$  of the colouring matter in the cold—with the following result: The portion which has been immersed shows an even pale tint equal in tone to

that of the upper portion; the level of the liquid is sharply marked off by a deep shade of blue, which attains its maximum at a height of about one inch from the surface, the colour then shading off with perfect regularity into the upper zone which, not having absorbed the solution, represents the dyeing capacity of the original calico. Experiment then shows that this powerful oxidation of the cellulose is due, not to any direct action of the air, nor of its oxygen, but to that of the carbonic acid which it contains; and further, in the absence of a liquid surrounding, containing excess of the bleaching agent, to that resulting from the oxidation of the fibre constituents which together react upon the hypochlorite slowly but continuously absorbed. This powerful action of carbonic acid is easily demonstrated by the experiment of moistening two strips of calico with the bleaching solution (4° B.) and plunging them, the one into an atmosphere freed from  $\text{CO}_2$ , the other into an atmosphere vitiated by respiration. Ten minutes' exposure, followed by the dyeing process, reveals a pronounced difference between the two, the shade of blue being considerably stronger in the case of the latter.

2. *Action of Heat*.—Experiments with dilute solutions (0°·5 B.) showed that up to 60° no sensible difference is caused by rise of temperature. Above this point, the temperature being allowed to rise at the uniform rate of about 2° per minute, and the strips being removed at the several points named, the following effects were observed after dyeing in methylene blue: 65°, no sensible difference from the original, from that point increasing in dyeing capacity, until after exposure to a temperature of 75° a marked increase was observed; after 85° the dyeing reached a middle shade; after 90° a deep-blue was obtained, with a marked weakening of the tissue, these effects still more pronounced after 95°; at the boiling point the cotton was entirely resolved into a white powder, which, however, after dyeing, is seen to have less capacity for taking up the colour than that modified as described under (1). The elementary composition of the cellulose thus modified was found to be C 43·6, H 6·8. The substance was dried *in vacuo* at 100° previously to the analysis.

3. *Action of Light*.—When calico moistened with solutions of bleaching powder is exposed, with exclusion of air, for ten minutes to the direct rays of the sun, a marked increase in the oxidising action of the solution is observed.

4. *Subsidiary Influences*.—Amongst these, M. Witz has investigated the effect of keeping the bleaching solution in continual motion, and other minor points, from which, however, we must pass, with this brief notice, to consider his main conclusions, practical and theoretical. The action of solutions of bleaching powder upon cotton is not confined to the colouring and other matters which are oxidised and removed in the form of soluble derivatives, but extends to the cellulose itself. By the extreme action of the hypochlorite upon cellulose it is converted into an oxidised derivative, obtained as a friable powder, outwardly resembling starch. The analysis of the products obtained by the prolonged action in the cold, in the manner described under (1), gave the following percentage numbers—

Oxycellulose.				Cellulose, C <sub>6</sub> H <sub>10</sub> O <sub>5</sub>	
C	43·78	43·47	.....	C	44·4
H	5·85	6·13	.....	H	6·2
O	50·37	50·40	.....	O	49·4

the difference from cellulose being such as to suggest to M. Witz the term oxycellulose whereby to describe this substance. Considered in relation to the sub-

stance described by ourselves under the same name the resemblance is sufficiently close to warrant an identical term, the latter being the product of a more drastic oxidation, being indeed a more highly-oxidised derivative. We propose to distinguish it from the oxycellulose of M. Witz by the prefix  $\beta$ . At the same time we would guard ourselves against attaching an undue importance to the terms which we use in the embryo stages of our investigations. We do not assert that in our  $\beta$ -oxycellulose we have a final product of the action of nitric acid under the particular conditions of the experiment, nor can we prove that it is actually a single or homogeneous derivative. Attaching to it, therefore, rather a group significance, and conceding that we may have in the product described by us an aggregate of several  $\beta$ -oxycelluloses, the term thus qualified may be allowed to stand. In his study of  $\alpha$ -oxycellulose, M. Witz has observed that it is attacked by boiling alkaline solutions, a portion being converted into soluble derivatives of a deep yellow colour. For this reason he is inclined to reserve the term in question to the insoluble residue, regarding the action of the alkali as evidence of the presence of a second substance in the oxidised cotton, which from its reactions, viz., that described above, together with its reduction of an alkaline solution of copper oxide, appears to be closely allied to the glucoses. At present we offer no opinion upon this interpretation, as M. Witz is engaged in the further development of his views. The view which he takes of the modification of the cellulose molecule under the action of the oxidising agents is in general terms as follows: Cellulose offers two main points of attack, the first being such as to indicate the presence of alcoholic OH groups, the second a capacity for that mode of union with the elements of water (hydration) which is accompanied by an alteration of molecular structure, *i.e.*, condensation and its reverse. The oxidation in question having no action upon the carbon nucleus, consists in a removal of H with a corresponding fixation of O, together with H<sub>2</sub>O, the latter being probably attended by the structural modification already noticed. The general result of the action is the manifestation by the product of the properties of an *aldehyde*, and in a certain measure also those of an acid. This view has, of course, been arrived at only by a study of the action in extreme cases, but is none the less applicable to the whole subject of bleaching by oxidising agents, as indeed can easily be demonstrated. The development of these properties, the result of the actual structure of the cellulose molecule, affords a key to the whole practice of bleaching and printing, which needs, we feel, only to be suggested to be followed up by all who have an acquaintance with the fundamental truths of chemistry. We will, before closing this part of our subject, consider certain consequences of these results. In M. Witz's paper will be found a complete classification of all the better known soluble colouring matters, into those (1) attracted and (2) repelled by oxycellulose, of which we may select certain as typical—

(1)	(2)
Methylene blue	Diphenylamine blue
Hofmann violet	Induline blue
Malachite green	Tropaeolines
Safranine red	Eosines
Fuchsine red	Indigo carmine
Bismarck brown	
Phosphine yellow	

Generally, therefore, under (1) we find the basic colouring matters, under (2) acids and such substances as require the intervention of the ordinary mordants. The application of these observations to the diagnosis of the condition of a cellulose in regard to oxidation we have already indicated. The two blue colouring matters known as methylene and diphenyl-

amine blue are to be recommended for the purpose, the results obtained being complementary to one another. The dyeing is performed in weak solutions ( $\frac{1}{1000}$ ) in the cold; the time requisite is about twenty minutes, this being a convenient standard. If the substance to be examined has been bleached with chloride of lime the following process of purification must be carried out prior to the dyeing: After thorough washing (1), exposure to dilute nitric acid (2° B.) for half an hour at the ordinary temperature; after washing (2), treatment with a boiling solution of sodium bisulphite (1° B.) for 15 minutes; after washing (3), treatment with dilute hydrochloric acid (2 B) in the cold for half an hour; and lastly (4), prolonged washing with water. It is noteworthy that oxycellulose is extremely refractory towards all influences which might be calculated to reconvert it into cellulose. No reducing action hitherto employed has in the least succeeded in accomplishing this regeneration. In the method of dyeing above described, the practical bleacher will doubtless see a ready means of detecting faulty work. In the earlier experiments of M. Witz he will see indicated the following points to be observed in his operations: (1) To construct the bleach-house so as to admit only diffused light. (2) To keep the goods well submerged in the bleaching solutions. (3) To avoid undue exposure of the goods to the air in contact with the bleaching solutions. (4) To keep the air of the bleach-house as pure as possible, purity meaning freedom from acid impurities, in which, in addition to carbonic acid, we must include in certain cases the acetic acid which pervades the atmosphere of printworks. (5) To avoid the use of strong solutions of bleach, the limit recommended under the ordinary conditions of working being a solution marking 0.5° B. (6) In goods which are bleached for printing, especially in the case of steam styles, to arrest the process before attaining a good white, leaving it to the subsequent operations, all of which are oxidising in their action, to effect the discharge of the residual tint. Other minor points it is unnecessary to detail.

One of the most prominent of the results of M. Witz's investigations is, to use his own words, to show that a trace of carbonic acid has the effect of rendering a solution of bleaching powder infinitely more active as an oxidant; and it will be convenient here to notice a process of bleaching, recently patented in this and other countries by Mr. J. B. Thompson, since it is a complete adaptation of the points here elucidated to a system of economical bleaching. It has been sufficiently shown that the action of the bleaching solution is not confined to the non-cellulose constituents of the raw cotton, but considerably affects the cellulose itself. Now this subsidiary result will obviously be considerably lessened if to the non-cellulose constituents, which are by far the more easily oxidised, the oxidising agent be presented in minimum quantities. This follows from the simplest laws of the influence of mass upon chemical attraction. Mr. Thompson bleaches by a successive supply of such minimum quantities, at the same time employing an atmosphere of carbonic acid, under slight pressure, to decompose each additional quantity. The exact *modus operandi* consists in saturating the goods, previously scoured and introduced into a keir of special construction, with a very weak solution of bleaching powder, the excess of which is allowed to run off, and the goods being sufficiently drained the gas is admitted. These processes are repeated alternately until the bleaching is complete. The theoretical anticipations of the advantages of this process are fully confirmed by experience of working on the large scale. The economy in time and chemicals, and especially

in manipulation, has proved very great, and the entire cost of the process has been reported by a practical bleacher to be under 30s. a ton. We refrain from discussing the more practical bearings of this method, as it is our intention, favoured by the kindness of Mr. Thompson and those who are associated with him, to demonstrate, at the next meeting of the Society, the entire process.

We pass on to consider briefly the second portion of M. Witz's researches. The conversion of cellulose into oxycellulose is attended by a modification in the attractive power of the fibre for the various metallic substances used as mordants. We can only consider the most remarkable of these results, a result which has an altogether exceptional interest. The absorptive power of oxycellulose for vanadium exceeds anything yet brought to light in the nature of a qualitative reaction. Calico converted into oxycellulose by the method above described is capable of withdrawing the vanadium from a solution containing 100000000000 of the metal, and the combination can be demonstrated by printing the tissue with aniline black mixture! No one can fail to be struck by a reaction of such extraordinary delicacy, and many will be sufficiently so to acquaint themselves with the details of an investigation which has established so remarkable a fact. Of great interest also to the calico printer are the applications of this oxidation of cellulose as a substantive printing process. A large number of oxidising agents exert a similar action upon cotton in converting it into oxycellulose. It is only necessary to localise the action of them, by any of the familiar methods, so as to produce a design in oxycellulose, to obtain by a subsequent dyeing operation a corresponding result in colour. A simple demonstration of this action and the mode of utilising it consists in writing upon paper with an ink composed of a solution of potassium chlorate acidified with hydrochloric acid. After drying, the characters are indelibly impressed as oxycellulose, and may be brought out by soaking the paper in a solution of one of the dyestuffs previously mentioned. It is noteworthy that they may be bleached away any number of times by exposure to a bleaching solution, and may be made to reappear in any colour by treatment in a dye-bath. This remarkable stability of the oxycellulose supplies an additional caution to the bleacher of cellulose goods, since it further shows the impossibility of correcting the over oxidation of the tissue, the use of an antichlore for the same purpose having been shown to be unavailing, in consequence of the resistance of oxycellulose to the action of reducing agents. Oxycellulose is thus shown to be an unchangeable mordant, and the results obtained by M. Witz open out the prospect of realising to some extent the truly ideal method of fixing colours upon cellulose, namely, by so modifying it chemically as to enable it to combine with these directly. M. Witz has also studied the action of a large number of other oxidising agents upon cellulose. Ozone and hydrogen peroxide rapidly effect its conversion into oxycellulose. The degradation of cellulose fabrics by long exposure to the air is also due to the molecular change accompanying the formation of this product. Witz also applies his results to the solution of certain special points in the printing of calicoes. The use of violet to correct the greening of aniline blacks, as suggested by Brandt (*Dingl. Polyt. Jour.* 215, 453), was successful by reason of the formation of oxycellulose in the printed portion, this acting as a mordant in the dye-bath. The tendering of the cloth often observed in the printing of chrome yellows is referable to a conversion into oxycellulose. The question whether a pattern has been printed by a discharge or reserve may be pronounced upon by an

examination for oxycellulose. Lastly, Witz shows that the presence of a caustic alkali in oxidising solution prevents the formation of oxycellulose, its oxidising action being confined to the production of soluble derivatives. Thus an alkaline hypochlorite or an alkaline solution of potassium ferriyanide may be used to effect oxidation in their several degrees when the formation of oxycellulose is especially to be avoided. Without entering into details, which would only be of special interest to those who make a close study of these subjects, we would point out, as a matter of general scientific interest, that the parallelism between the investigations of M. Witz on cellulose and of ourselves upon jute, and the compound celluloses of which it is a type, has been of the closest nature. Not only have they been coincident in time, but the point of departure was similar in the two cases, viz., the disintegration and discolouration of bleached fabrics, as a result of an oxidation in the bleaching process, further developed in the process of steaming. Their point of contact lay in the investigation of the two forms of oxycellulose above described. On the occasion of our visit to M. Witz we made with him a study of the cellulose isolated from jute by the method of chlorination. This has been shown to differ in composition from ordinary cellulose, the analytical numbers obtained by us showing a close resemblance to those obtained by M. Rosenstiehl for  $\alpha$ -oxycellulose.

Cellulose from Jute.			$\alpha$ -Oxycellulose.

In confirmation of these results we found a close similarity in properties, *e.g.*, in tinctorial capacity and in the power of reducing an alkaline solution of copper oxide. Jute cellulose appears therefore to be oxycellulose. The same is doubtless true of a large number of the so-called celluloses used in paper-making, which are isolated by chemical treatment from compound celluloses, and M. Witz's results will doubtless prove to have an important bearing upon this branch of the cellulose industry.

In conclusion, we will briefly describe the results of the preliminary study of the oxidation of cellulose by means of a solution of potassium permanganate, to which sufficient caustic alkali was added from time to time to prevent the solution from becoming acid. The cellulose was employed in the form in which it is precipitated from its solution in the Schweitzer reagent, by the addition of acid. After washing, this was suspended in the solution of permanganate, of which further quantities were successively added until the whole of the cellulose was converted into a soluble derivative. This was then isolated by means of its lead compound, being purified by fractional precipitation, and thoroughly washing the precipitate. On decomposing this with hydrogen sulphide, filtering from lead sulphide, and evaporating, a strongly acid gummy body was obtained, which dried at 110-120° to a yellow friable solid. This was analysed with the following results: 0.2204 (deducting ash) gave 0.3038  $\times$  0.004 ( $\text{CO}_2$  determined in the ash) and 0.0622  $\text{C}_2\text{O}$ .

The resemblance of this body to Fremy's metapectic acid is very marked. The entire series of bodies of which metapectic acid is the extreme member are obviously oxidised derivatives of cellulose; and in the two methods of oxidising cellulose which we have studied, viz., by nitric acid and by alkaline perman-

ganate, we have arrived at products presenting a close relationship to bodies of the pectic series. We are prosecuting these researches in the hope of throwing some light upon an important group of natural products which as yet remain without the pale of chemical classification. This brings us to the conclusion of our subject. We have only to hope that it will contribute in some measure to the building up of the fabric of cellulose technology, by suggesting directions in which work is so urgently needed.

The discussion was adjourned to the meeting in May, when Mr. Cross will demonstrate the processes referred to in the paper.

After the reading of the above paper a conference was held on

### STANDARD METHODS OF SAMPLING MERCHANTABLE PRODUCTS, OF ANALYSING THEM, AND STATING THE RESULTS.

The CHAIRMAN: We have to discuss this evening, as the circular which has been sent to you indicates, the desirability and practicability of arriving at a national or international agreement concerning the methods of sampling, the methods of analysis, and the modes of returning the results of ores, raw products, and chemicals. This important subject has already been discussed by the Liverpool, London, and Newcastle Sections of our Society, and we have thus the great advantage of knowing the views of many eminent chemists, and of men well qualified to express an opinion on it. There appears to be no doubt in the minds of most of the gentlemen who took part in these discussions that such an agreement would be very desirable, and this needs not to surprise us. We all know that there exist in many instances various methods of analysis for the same substance, and we all equally well know that the results of an analysis of the identical substance, but obtained by different methods, may lead to different results. It does not therefore require much consideration in order to come to the conclusion, providing that such an agreement is practicable, that it would be a most desirable one, and I think that it will be superfluous to discuss this evening the question of desirability. The difficulties which present themselves to your minds, and the means of overcoming these difficulties in order to come to a satisfactory agreement, ought to constitute the principal object of our discussion. We may perhaps also dispense this evening with the enumeration of the great differences and discrepancies which no doubt many of you have met with in your various experiences, and which resulted either from the different methods of taking samples or from the different methods of analysis or from other causes. However interesting these communications might be, I think that we may fully accept as an established fact that the present system has its great disadvantages. I propose, in order not to waste your valuable time, that we consider *seriatim* the following questions, which I beg now to submit to you, and after having heard your views, that we then bring forward at the next meeting resolutions embodying your replies and opinions. I only desire to make one exception, as I intend, with your permission, to bring later on a resolution before you in reference to the first question. (1) Is an international or a national agreement more feasible? (2) Does a national agreement meet all purposes, at least

as far as the interests of this country are concerned? I beg you to carefully consider these two questions, as there may be some insurmountable difficulties of arriving at an international agreement, while the less ambitious scheme of arriving at a national understanding might be far more practicable and equally as useful. (3) What are your opinions concerning uniform methods of sampling, and how could an agreement be arrived at? (4) What are your opinions concerning uniform methods of analysis? (5) What are your opinions concerning uniform methods of returning the results? (6) In the event of the appointment of a representative committee, (a) how should that committee be constituted? (b) Should it be a permanent one? (c) What organ do you consider the most serviceable to give effect to the conclusions to which that committee might arrive? (7) If standard methods have been agreed upon, and have been published by the authority of that committee, should these be considered binding to either chemists, buyers, sellers, or consumers, or should they be only considered as recommendations? However successful we may be in coming to some agreement, it would be in my mind not alone not advisable, but also almost impossible to make any agreement in any way binding on chemists, buyers, sellers, and consumers. Such an agreement, of whatever nature it might be, ought to be only considered as a recommendation to the chemical profession or others, but I do think that any recommendation made by a representative committee would be in most cases adopted. I have now the pleasure of calling upon Mr. George E. Davis to state his views upon the subject.

Mr. GEORGE E. DAVIS: I think, Mr. Chairman, that there are very few present who will disagree with you in your remarks that an international method or methods for sampling goods, for their analyses or assay, relating also to the method of returning the results, would be a very desirable thing; but in each of the discussions held at those Sections where this subject has been considered the means whereby this most desirable end could be accomplished has been avoided. No doubt it is a most difficult question to approach, and I am not sure whether every difficulty could not be met by attention to the methods of sampling and the modes of returning the results of the analysis or assay, leaving the analytical chemists still responsible for discrepancies if they choose to perform inaccurate work by incorrect methods. An enormous amount of abuse has been poured upon the heads of chemists on account of discrepancies, which without further inquiry would make the outside public believe that chemistry was not a very exact science. But may not much of this be due to the method of sampling? My experience in works of very varied character leads me to positively assert that it is in many cases the sampling which is the inexact process, and when several chemists have been given samples, in which every care has been taken to render them homogeneous, their results have not been very far from each other, in most cases certainly within the limits of error of experiment. It would, in my opinion, be a step in the right direction, in the case of samples to be sent to more than one chemist, if instructions as to the methods of sampling were issued. It should be made a point that the contents of the several bottles be well mixed, ground up either in a mill or in a mortar, passed through a sieve, and the homogeneous mixture rebottled. Of course there are substances which could not be treated in this way. Substances which are deliquescent or hygroscopic would need special treatment, as would also pasty substances, but this is a matter of detail which would have to be worked

out, the main point I would wish to insure being that when samples were to be examined by different chemists, possibly one acting for the buyer and another for the seller, it should be an undeniable fact that both were working upon identically the same substances. Of course, one can never expect to be able to cope with what I may term fraudulent sampling, if the sampler, say in sampling burned pyrites, peppers the sample with a little copper precipitate, or if in sampling a weak manganese ore he manages to insert a tolerable quantity of good 80 per cent. into the bottle, or in sampling bleach he contrives to save the lumps and lose the dry dust, the fault does not lie with the analyst, and the injured party has his remedy at common law. An agreement upon the methods of returning the results of analysis would be most beneficial, and in my opinion be one way out of the difficulty of forcing standard methods of analysis upon unwilling minds. Take, for instance, the question raised at Liverpool by the chairman of that Section regarding the estimation of the available peroxide of manganese in manganese ores of commerce. He says, "We found it desirable to use the protoxide of iron test," which no doubt, though in every respect at that date admirably suited to the valuation of its chlorine producing power is now nevertheless a little misleading, and a test which does not accurately represent its value even to the chlorine producer, while for such purposes as the manufacture of spiegel or ferro-manganese the method used by the alkali makers could not be entertained at all. In fact, I know of a case in Manchester where a manufacturer bought a parcel of "manganese" by the usual test, but the seller, having found that it would be used for sulphate of manganese making, had it analysed for total manganese present, and this departure led to no small dispute between the two parties. This could have been prevented, even with our present methods of sampling, by an agreement as to the best methods of stating the results. It is in cases of this kind that the difficulties of insisting upon standard methods come in, as the seller as well as the buyer has to be protected, and in the methods already quoted there would have to be a standard method for the use of chlorine producers, another method for the use of ferro-manganese makers, and another for the maker of sulphate of manganese, where the maximum of protoxide or carbonate is an advantage. Surely chemists may be left to estimate the active principles of these substances for the various purposes of trade, if the particular trade in question will only say how it desires the results expressed, but it is obvious that owing to the impure and varying nature of all minerals and raw materials, one could not depend upon a factor for converting the results of one standard method into the probable results which might be obtained by another. Acetate of lime is a substance which has caused much dispute. Some chemists estimate the amount of acetic acid in it by distilling with phosphoric acid, while others use a method known as the sulphate of soda method, giving results some 8 to 10 per cent. higher than the former. Of course buyers and sellers know the £ s. d. difference between the value per unit of these tests, but the question may be fairly asked whether a chemist is doing right by certifying that a sample contains a certain percentage of acetic acid when he knows full well that it does not. The analysis of manures, potash salts, all raw products, and finished articles, may, in my opinion, be all dealt with in the same way, viz., by an agreement as to the method of stating results. My views are not at all favourable to the standardisation of methods, without such methods are founded upon absolute scientific reason-

ing and experiment. Let me explain by calling attention to the testing of crude benzol, mentioned by Mr. Watson Smith, at the Liverpool meeting. Quite recently I had occasion to send several samples of crude benzol to various chemists, and by the ordinary test they all returned the certificates within a very few points of each other, but they also mentioned that the sample was an abnormal one, and that they had modified the "usual test," and by this modification, I am glad to tell you, they were again within very few points of each other. This circumstance leads me to suppose that chemists are capable of taking care of their reputation, and that there is but little need for fixing standard methods, at least for many substances. One thing I would earnestly like to see abolished, and that is the host of ammonia-meters, aerometers, Twaddell's and Baumé's hydrometers, the old Fahrenheit thermometer, and all barbarisms of this kind, and to place in their stead the ordinary specific gravity glass, taking water at 1000 as the basis. I think this might be done by publishing a bold table of the equivalents of the various hydrometers in specific gravities, in the Journal of the Society, and continuing to publish and exhibit the same on the cover of the Journal for months, or even years if necessary. In conclusion, I think national methods for accomplishing the above objects are attainable; but not international ones.

Mr. MELLOR: I am not prepared to endorse the suggestion that our Society should recommend the adoption of standard methods of analysis. Chemistry is so vast a science, consisting as it does of almost an infinite variety of truths or facts, that it admits of the attainment of the same results, accuracy of analysis, by many and varied processes. Chemistry is a growing science, and to limit it, to confine it, to chain it down to the prescribed limits of "standard methods of analysis," would most assuredly interfere with the free growth and development of the science that we all love so well. But I think that our Society could well adopt the recommendation of a more perfect and therefore uniform system of sampling than that which now prevails. From some experience I am prepared to affirm that difference of analysis is more the result of imperfect sampling than of inability in the analyst or of errors in the methods of analysis. In proof of this I may state a recent experience. A cargo of mineral arrived in the Mersey a few months ago. A sample of it submitted to the buyer gave 29 per cent. of metal—the certificate of it from a foreign chemist showed it to contain 33 per cent. of metal—but when the whole cargo arrived at its destination, and it had been properly ground and sampled, the whole bulk contained 40 per cent. of metal. All the analyses in this case were correct—it was the sampling that was at fault. Simply as suggestive, and as my contribution to this conference, I name the method of sampling minerals as adopted at Patricroft. On the arrival of the mineral it is weighed, and every tenth portion—whether of bags, or casks, or other packages, is laid aside. This tenth part is afterwards ground, mixed with a spade on the floor, and then passed through a rather coarse sieve to insure its more complete mixing, and then the foreman takes an iron tube, about 4ft. long and some 1½ in. or 2 in. diameter, and probes the heap of ground mineral at top, bottom, sides—in a word, all over it. The sample thus obtained is then divided into three portions—one for the buyers, one for the sellers, and one for reference in case of dispute—and all carefully sealed up. One source of error is the question of moisture, and the mode that it is to be dealt with ought always to be agreed upon between buyers and sellers, and the analyst ought to be informed of the arrangement

entered into. Must the sample be dried in a water-bath for twelve hours at 100° C., or is the chemist to dry the sample in his own way, and in his own time, and in an open dish over an open furnace? Clearly much difference of results would be obtained if clear and definite instructions on these points were given to the analytical chemist. Another source of error, and the fruitful cause of difference of results obtained by chemists, arises from the loose and indefinite way in which the words "assay" and "analysis" are so frequently employed. Buyers and sellers, and the chemists acting for each, ought to know each other's minds clearly on this matter, and in all agreements between buyer and seller and instructions given to chemists the words, contents "fire assay," or contents by "analysis by the wet or acid process," ought to be introduced. It is only necessary to point out that in all cases of volatile metals, of which antimony and bismuth may be taken as types, even in the most skilful hands the difference in the results obtained between "fire assay" and "analysis by acid process" is from 2 to 3 per cent. of metal contents. I fear that the question of an international agreement as to the adoption of standard methods of analysis and of sampling is at present not practicable, the conversion of kilos. and metres into pounds and inches of itself presenting a grave difficulty, but I think that it is within the power and scope of our Society to recommend the adoption of some uniform and standard method of sampling for the United Kingdom; and if we succeed in this, we shall be justified in inviting other nations to join us. Let us aim at realising the attainable.

Professor Roscoe wrote—

"In consequence of the meeting of the Literary and Philosophical Society, Professor Roscoe regrets that he cannot be present at the sectional discussion on methods of analysis. He wishes, however, through Mr. Watson Smith, to express his opinion as to the very great importance of the question, and the desirability of the full discussion. He feels unable to make any remarks on the advisability of fixing definite rules for sampling, but it is clear that correct sampling is an all-important factor, and that if some well-defined methods can be laid down and generally adopted the result must be of value. As regards the further question of the Society laying down the law as to methods of analysis, he sees much greater difficulty, and he thinks that this, if done at all, should only be done after very careful consideration. What is really needed is an appreciation, both by the analyst as well as by the buyer and seller, of good and correct methods. Until the public as well as analysts are well educated in this respect there will always be a demand for uncertain or even inaccurate methods, some of which are still in vogue. To fix upon certain processes is to do away with the freedom and discretion of the analyst, and possibly to introduce the very evils it is desired to avoid. Inasmuch as new and improved methods are constantly being introduced into science which a stereotyped system would find difficult of adoption. Hence Dr. Roscoe is inclined to believe that the most advisable course for the Society to take is rather to point out those methods which are faulty, and suggest others which are free from errors, than to lay down any hard and fast lines with regard to analytical methods. He would also remind the Section that the Institute of Chemistry has for its object the attainment of the same end, viz., the reliability and accuracy of commercial analyses, by a somewhat different means, viz., the certifying of competency on the part of the analyst, by examination or otherwise. Dr. Roscoe feels that, after all, the best way to secure a good analysis is to employ a good man to do the work, and he would rather trust to his discretion and skill in choice of methods than to the less educated person working by rule."

MR. WATSON SMITH: Since speaking in Liverpool and writing to London on the subject of standard methods of analysis and sampling, I have thought more on the subject, and my earlier views, never very clearly formed, and therefore never very clearly stated, as to the possibility and desirability of the general adoption of such standard methods, have received considerable modification. I confess I have now almost come to the conclusion that, on the whole, we may perhaps do best to leave the analytical methods to look after themselves—to commend or condemn themselves, as the case may be, in the belief that the Darwinian law of the "survival of the fittest"

will also extend its truth to them. If it be said that as improved methods appear those methods employed in the standard code could be replaced or altered, I would reply, "Not without much delay and great difficulty, for according as the alterations involved would for the time affect manufacturer or purchaser, seller or buyer, so would the one or other class contest the innovation." But in the proposed international scheme one analytical method was to be fixed upon for each kind of quantitative determination, and all the chosen methods were to become obligatory as regards commercial products. As regards this kind of compulsion another view presents itself, and not a pleasing one, of analysts of commercial products treated like animated testing-machines, worked by a select committee. However, do what we will, follow what course we please, place ourselves under the control and guidance of whatever select committee of chemists we like, we cannot cause to be infused a single ray of life or intelligence into analytical methods themselves, nor can we teach a test-tube, a chemical balance, or a burette how to think! It is to be hoped, though, that with the increasing educational advantages and means offering, and likely to offer yet more abundantly in this country, that chemists in plenty will be found, both sufficiently instructed and experienced to discriminate between the reliable and unreliable in analytical methods, and with minds sufficiently enlightened to choose the good rather than the bad. The Institute of Chemistry deserves to be upheld and supported more generally than it is, for it does a good, albeit a quiet work, in practically discriminating between those young men who have received an education fitting them to become efficient analysts and those who have not, and in doing this adopts a very safe, because a very high, standard in its examinations for the associateship. If a buyer or seller wants a reliable analyst, let him run his eye over the list of the Institute and select there, if he be at a loss. Once more returning to the compulsory scheme, and now referring to the proposed select committee, whose office it would be to choose the methods and issue them, it seems to me the time has scarcely come yet for us to subject ourselves to what might develop into something analogous to a kind of chemical priesthood! I think, in short, the attempt through the medium of a select committee, or otherwise, to impose the adoption of a list of compulsory analytical methods on chemists of education and experience would appear to the latter very objectionable. I can both understand and appreciate the publication and recommendation in the columns of our Journal, or of any other journal, of serviceable and accurate methods, and also the exposure of unreliable and deceptive methods, but do not let us, as it were, take the intelligence, honour skill, and understanding of the chemist from him and place them in his standard solutions, his burettes, and his evaporating dishes! The value of sets of rules for sampling various chemical products would be very great. Of special advantage would they be for those whose experience as regards outward appearances of such products is not yet sufficiently formed to enable them to guard themselves against the tricks that are available to professional samplers, making such samplers, in the hands and employ of, say, unscrupulous floaters of companies for exploiting minerals or mineral deposits, extremely dangerous persons. It is astonishing what some of these mineral samplers can do in the way of picking samples from one and the same heap. But even to some masters and proprietors such rules would be of great value (and to this I can testify from my own observation) to protect them from the wiles of certain foremen and

managers. I may ask, what is the use of employing a chemist at all in cases of such a kind, for he may only certify the strength of an unfair specimen. If any chemist wants to try an instructive experiment in this line, let him go over a heap of rather badly-made salteakes from the ordinary pot and furnace, and take first a sample from every part with a spoon, and secondly another sample with a spade (i.e. large lumps with small), and test both separately, and he will find considerable difference in the percentages of sulphate discovered in the two specimens.

Mr. J. CARTER-BELL: This subject of standards has been for a long time in my thoughts. Many years since I published in the *Chemical News* a letter calling attention to some very inaccurate analyses of water, which water had been analysed by five different chemists, of whom no two agreed in their analyses. I then suggested that some standard methods should be employed. It is of no use, Mr. Chairman, to bring before you instances of incorrect analyses, as their name is legion. What one ought to do, is to make some suggestions and to give some sensible practical remarks. The question of sampling has been so ably taken up by Mr. George E. Davis and Mr. Mellor that it leaves nothing for me to say upon that point. It is unnecessary for me to state that I heartily agree with all that has been suggested by these gentlemen. Mr. Davis says that he does not think that the analytical chemists are at fault. It is very kind of him to speak a good word for a much-abused body of men, expected to be immaculate regarding the analyses performed. I do not agree with Mr. Davis on this particular subject. After an experience of twenty years' analytical practice, I do not find that "chemists in their little nests agree." My strong opinion is that we do want some recognised authority that should be able to give to chemists some standard methods of analysing commercial products. I think this meeting might learn a lesson from the Society of Public Analysts, who at this present time have formed a committee for the purpose of ascertaining the best method of analysing milk, for great variations occur even in the analysis of so simple a thing, for one man bases his conclusions upon weighing the solids, not fat, another weighs the fat, while a third weighs both. To settle which is the best method a committee of thirteen chemists has been formed, a sample of pure milk and one of adulterated milk are sent to each of the thirteen chemists, the analyses are made by each chemist according to his own particular plan. As the committee is still sitting it would be premature to state what will be the results. I cannot see why this Society, the Chemical Society, and the Institute of Chemistry should not form an influential committee to thoroughly investigate this question of analysis. To save time I will only give one illustration, and that shall be the analysis of sulphur pyrites. It is well known that chemists differ in the estimation of the sulphur to as much sometimes as 2 per cent. I think the chemist cannot complain and say that he does not receive the sample in a finely-powdered condition, so that there can be no excuse on the question of sample. The difference arises in the analysis from one chemist using the acid method while another uses the fusion process, and the result is the analyses cannot agree. Supposing a committee were formed, and a sample of two or three pounds of finely-ground sulphur ore obtained, which should be most accurately analysed, and every element in it determined. The ore should then be put into thirteen or fourteen bottles, and sent to as many chemists, with a request that they should estimate the moisture and the sulphur by their own processes. If when the returns were sent in it was found that a

large majority were close to the standard, and that they had all used a similar process, I think then the committee might safely say we recommend this process. The method should be published, and written out in the most minute detail, so that a chemist, if he had never performed such an analysis before, on reading over the method of the committee, would have no difficulty in returning correct results. To me it seems childish to say that the chemist will become a mere machine. If he is told what to do, and how he is to do it, instead of being a machine the chemist would have more time to devote to other work instead of wasting his time upon what is already known.

Dr. WATSON: There are some people who appear to imagine that it is possible to give complete instruction in every matter relating to the arts and manufactures by means of treatises or textbooks. My experience leads me to an opposite conclusion. I imagine most of you will agree with me that the knotty points that one meets with in one's own business are generally most skilfully avoided in such treatises, or infallible guides, and I am afraid no number of conferences and committee meetings would suffice to supply the expectations of those who would answer all the queries put to the meeting in the positive. Nevertheless the discussion of them cannot fail to do good apart from any particular action to be taken by our Society or our Section of it, by forcing on the attention of those who buy and sell raw materials and manufactured articles the importance of paying increased attention to that part of their contracts that relate to sample and assay. In the abstract it would appear as essential that a form of contract for raw materials or chemicals should define the method of sampling and assay as it is that it should fix the price or the other terms. Practically, this is met by there being in most cases a custom of the trade in sampling, and by the existence of faith in the power and willingness of the analyst to do what he undertakes to do. Those who have set in motion the discussion of these questions of standard methods tell us that the custom of the trade as regards sampling many articles is not a proper one, or that both a proper and an improper one exist, and further that some analysts employ methods of analysis or assay that are not to be depended upon, and thus they explain the discrepancies that occur between the results of the examination of the same parcel of certain commodities by different analysts. I daresay that is so, but I am sure also that other elements in these discrepancies are the idleness and carelessness on the part of samplers, and ignorance and incompetence, and what I had better perhaps call *bias* on the part of the analyst. No textbook instruction will suffice to eradicate these. With regard to most of the heavy products and raw materials of industry proper methods for both sampling and analysis are well understood, and do not remain to be discovered, although it is doubtless true that these proper methods are not universally employed. Allowing that it is desirable that all the transactions in a particular commodity should be conducted with reference to one standard method, and I am certainly of that opinion, I cannot see myself that it is possible for our Society to do more, at the most, than offer suggestions to the trades concerned. We can discuss, promote investigation, and suggest improvements, but after that we must leave it to those commercially concerned to adopt our suggestions. Our Society, by its constitution, is admirably adapted to do this. For example, suppose after we had heard Mr. Carter-Bell's admirable paper on this very subject of standard methods, where he entered into detail with regard to analysis and valuation of gas liquors, and it had been published, we

had had a meeting called specially to discuss the proposals in that paper, I doubt not that a number of persons interested would have attended, and we should have had a discussion among them that would probably have so threshed out the subject as to supply what might be adopted as a standard method for the valuation of gas liquors. As a practical way of promoting these objects I suggest the following as a feasible scheme. The general council should draw up a scheme allotting the discussion of the subject that relates to special raw materials or chemicals to each Section, so as to divide the labour. Pyrites to one, bleach to another, alkali to a third, and so on. By this division of labour time would be saved. The sectional committee would then arrange for the most thorough ventilation and discussion of the whole subject allotted to it, and afterwards draw up a report, and if possible definite regulations such as might form a standard for the trade. Our Journal would, in the ordinary course, publish reports of these meetings and the formal result of the discussion. So far I believe our Society can go. It can by its representatives come to definite conclusions and publish them, but it cannot give them the force of law. Even though these standards were not authoritatively adopted by the trade, they could and would probably be stipulated at first by buyers, who were perhaps not quite able to form an independent judgment, as a system in which they could have confidence, and be easily referred to as the Society of Chemical Industry's method. Taking the questions in our circular *seriatim* I would say (1) that I believe that when an article, uniform in its physical condition, is a large article of commerce, it is both practicable and desirable that a general agreement should be attained with regard to the way in which samples are taken, but I doubt if such a general agreement can be attained by any efforts of our Society. (2) No analyst ought to issue a certificate of analysis unless he is satisfied that a proper procedure has been followed. If he issues a certificate in the contrary belief he does a dishonest thing. There are two ways of diminishing dishonest practices. The first is by precept and example; the second by pains and penalties. Our part is evidently the former. If we do the work well, exposing erroneous practices, and providing for the analyst methods that have the approval and recommendation of our Society, I think that analysts will find it safer and more comfortable to avail themselves of these methods than to employ others, perhaps equally accurate, but which have not such approved recommendation. In this way, I believe a pretty general agreement may be arrived at. Further, I can see no reason why such a general agreement should not become an international one, but it would become so by operation beyond the scope of our Society. (3) This question implies that there are in some cases variations in the methods of returning results. If the several methods involve nothing contrary to truth they may be all admissible, but I think our Society should draw attention to variations of this kind calculated to deceive, such as the well-known case of the so-called Liverpool custom, in the alkali trade, and set its face against them. (4) As I have said before, I believe that our general council and the sectional committees are in a position to do all that we as a Society can do, and that to appoint special committees for the purposes of regulating the course of trade in this respect would be to go beyond the legitimate functions of the Society of Chemical Industry.

Mr. GRIMSHAW: In the first place I may say that my own view inclines very much in the direction pointed out by Mr. Davis and Mr. Mellor. I think with Mr. Bell in one respect that the formation of a committee to decide upon accurate methods of

analysis would be a very useful institution, but I do not think that the duty of that committee should further proceed in the way of asserting that analyses by one or even two particular methods should be adopted, as I am of opinion that no committee would be able to carry such methods into law. The great difficulty, to my mind, which has stood in the way of uniformity in the methods of analysis is simply the fact that there are "buyers" and there are "sellers." A buyer will always choose a method of analysis which gives a low valuation, and a seller will choose a method which gives a high one, a very good illustration of which you will find in relation to the "soda test," mention of which was made in the discussion at Liverpool. The Liverpool chemists appear to adhere to the old atomic weight of sodium, the consequence of which is that there is actually a difference in the results between Liverpool and Newcastle simply because in the one place a different atomic weight is adopted from the one in use at the other. Yet even this need not lead to any confusion between the buyer and seller, any more than a difference in the result given by different processes, if it is known by what standard the sample has been analysed, because, this being so, the value of the article can be assessed *pro rata*, according as the numerical result is known to be high or low, under those particular conditions. Leading from this point, we must not forget that in deciding on the method of analysis a chemist is very often biased in favour of a particular method, and it will always be the case that an analyst who has a great deal of work on his hands, will as far as he is able choose the most simple operation of those in use, and it seems to me that in many cases if that operation is one which does not give quite so theoretically correct a result as some other, yet it may be fairly considered sufficient for the purpose, because if it is a process which will give uniform results on its own basis, it need not attain to a superlative pitch of scientific accuracy so long as by its aid we are able to form an equitable judgment upon the results. The valuation of crude acetate of lime is a case in point. The sulphate of soda process may not give so accurate a measure of the real percentage of acetic acid as the distillation process, when very carefully conducted, though I do not think the difference is great, as is sometimes asserted, but it is much more easy and rapid of execution, and gives very concordant results, and we therefore cannot wonder that the small amount of time and attention which the sulphate of soda process demands compared with any process of distillation, has recommended the former to analysts who have a living to obtain. At the same time it is very desirable that a reliable comparison of these two methods of valuing this important chemical product should be made. I am myself working on this subject, and hope at some future day to be able to place my results before the Society. I practically agree with Mr. Davis that if we could only secure "good sampling" we should really be in a fair way to overcome all our difficulties, but in sampling there is, of course, a bias, and that you cannot eliminate by any method of legislation or the formation of committees. If methods of sampling were, however, taken under consideration, I think it would certainly come fully within the province of our committee to recommend for adoption certain modes of procedure for obtaining accurate samples of all the more important materials known to industrial chemistry.

The CHAIRMAN: I am glad to hear that Dr. Roscoe and Mr. Watson Smith agree with me, in case an agreement is practicable, that the same ought not to be a compulsory one. After the many valuable remarks we have heard, we may fairly conclude that

an international agreement would not be agreeable, but that a national one would be far more feasible. I therefore beg to move the following resolution: "That in the opinion of this meeting it would be practicable and very desirable to attain a national agreement on standard methods of sampling ores, raw products, and chemicals, but that an international agreement would be at present impracticable."

The resolution, which was seconded by Mr. DAVIS, was put to the meeting and carried unanimously.

The conference was then adjourned until May 6th.

## Glasgow and West of Scotland Section.

Chairman: Ed. C. C. Stanford.

Vice-chairman: Professor Ferguson.

### Committee:

George Beilby.	Professor Mills.
Professor Crum Brown.	James Napier, jun.
J. Christie.	T. L. Patterson.
Dr. John Clark.	J. B. Readman.
Professor Dittmar.	Dr. Edmund Ronalds.
George G. Henderson.	F. J. Rowan.
George M'Roberts.	R. L. Tatlock.
James Mactear.	Dr. William Wallace.

Hon. Treasurer:

J. J. Coleman, 45, West Nile Street, Glasgow.

Hon. Secretary:

Dr. James J. Dobbie, Chemical Laboratory, University of Glasgow.

### MEETINGS FOR 1884.

MAY 13TH.—(1) On Different Methods of Producing Cold Artificially. By Mr. Coleman. (2) On the Composition of Tobacco. By Dr. Clark.

Meeting held Tuesday Evening, March 11, 1884.

MR. ED. C. C. STANFORD IN THE CHAIR.

THE CHAIRMAN intimated that the Section now numbered 137 members. When it was formed there were only 114 members of the Society resident in Scotland. Sixty-six new members had joined during the month that the Section had been in existence, bringing up the number of Scotch members of the Society to 180.

## ON THE EFFECT OF TEMPERATURE IN DYEING.

BY EDMUND J. MILLS AND A. G. RENNIE.

VERY few measurements have been made of the influence of heat in chemical change. Hood (*Phil. Mag.*, Nov. 1878), calculating from data previously published by Harcourt and Esson, was of opinion that chemical effect is proportional to the square of the temperature; and this result was afterwards confirmed by Warder. Our own object has been to make some preliminary measurements of the effect of temperature in dyeing. For this purpose we selected purified cashmere wool (in the piece) and a well-crystallised sample of rosaniline acetate. The first series of

experiments was performed in such a manner as only to saturate the wool at successively higher temperatures. To this end we took a glass bath holding in every case 200 cubic centimetres of water, heated to and kept at the desired temperature within a few hundredths of  $\pm 1^\circ \text{C}$ . A standard solution of the acetate was prepared, containing 0.1 grm. in a litre of water. The pieces of wool to be dyed averaged about 0.5 grm. each, and contained 12.73 per cent. of water. These were first introduced into hot water, in order to prevent the formation of air bubbles, drained rapidly, and inserted in the hot experimental bath, in which they were kept each for one hour. During this time rosaniline solution was slowly added, with constant stirring, until at the end of the specified time a red tint was just perceptible at the edge of the liquid. In some cases a little water of the same temperature as the bath was added to make up for a slight evaporation. The following table contains our numerical results, and a corresponding set of numbers calculated from the data marked with an asterisk, by means of an equation referred to below:—

Colour absorbed per gramme. Cubic centimetres.	Cubic Centimetres. Calc.	Temperature. C.
—	0.00	—1.46
0.41	0.37	+1.50
0.90	0.90	6.25*
1.25	1.75	16.25
2.18	2.18	26.25*
2.42	2.18	36.25
2.21	1.82	46.25
1.21	1.21	56.25*
0.52	0.56	66.25
0.22	0.22	86.25*

It is already known (Mills and Thomson, *Chemical Society's Journal* 35, 28) that at some temperature approaching the boiling point of water, and if adequate time be given, rosaniline salts undergo dissociation, producing, if their solutions be very weak, completely colourless liquids. It is in fact evident, as well from the numbers above given as from the dyed samples themselves (exhibited to the Section), that throughout a considerable range of higher temperature the tendency of wool to absorb colour is more or less counteracted by a dissociation stress, though in our own experiments the time was too short for much actual dissociation.

If we assume Hood's law, and consider the absorption of colour as well as the dissociation stress to be chemical effects, the combined effect in these experiments should be proportional to the fourth power of the temperature. As the temperatures from 6.25 to 66.25 were taken at equidistant intervals, it is easy to examine the differences of rosaniline solution thereto corresponding. The sum of the fifth differences proves to be  $-0.7$ , or very nearly zero—a criterion of a quadric curve. The equation of this curve is—

$$y = b(t + 1.46) - c(t + 1.46)^2 - d(t + 1.46)^3 + e(t + 1.46)^4$$

where  $y$  is the amount of colour absorbed in cubic centimetres,  $t$  is the temperature, and  $b, c, d, e$  are constants of condition. The logarithms of these constants are—

log. $b = 1.1068445$	log. $d = 5.4194377$
log. $c = 3.1009246$	log. $e = 7.4435168$

Hence we have calculated the position of the following points of interest, viz:—

Temperature C.	Effect.
—1.46	No colour deposited.
+31.11	Most colour deposited.
81.15	Very little colour (0.7 cubic centimetre) deposited.

Beyond this last temperature more colour is gradually taken up, the calculated amount being 1.30 cubic centimetres at  $100^\circ \text{C}$ , so that the advantage still lies

greatly with the temperature  $31.11^{\circ}\text{C}$ . At this point 1 grm. wool is dyed a fairly deep shade by 2.23 cubic centimetres = .02 per cent. of rosaniline acetate. A drawing of the curve is subjoined.

Our next series of experiments was carried out in a manner in all essential respects similar to the above, excepting that we now employed in every case a grammé of wool and a constant quantity (.0005 grm., i.e., excess) of rosaniline salt, and reduced the time to a quarter of an hour. The remaining salt in solution was determined colorimetrically. On examining the numerical results, we found that, owing to the appearance of two subsidiary inflexed curves between about  $39^{\circ}\text{C}$ . and  $67^{\circ}\text{C}$ . (the former temperature being that of greatest observed deposition), it was not possible, without an enormous series of experiments, for which we had not sufficient leisure, to work out a complete application of Hood's law to this case. We have therefore contented ourselves with examining approximately the most interesting points, as regards dyeing effect, in this curve. We find (1) that at no practically attainable temperature near to  $0^{\circ}\text{C}$ . does colour cease to be deposited; (2) at about  $39^{\circ}\text{C}$ . the greatest amount (.09 per cent.) is taken up; and (3) at about  $82^{\circ}\text{C}$ . the curve falls lowest to the axis of no colour. Thus the results of using an excess of colour have been to greatly widen the range of temperature within which colour is taken up, to increase the general dyeing effect and to shift the point of greatest deposition (as might have been expected) about  $8^{\circ}\text{C}$ . upwards, and to doubly reverse it thereafter. The greatest influence of dissociation is, however, felt at much the same temperature as before. We have also made a short series of experiments, exactly resembling these last, with mauveine in excess. By calculating from the data nearest to  $0^{\circ}\text{C}$ ., we find that colour would cease to be taken up at  $-23.8^{\circ}\text{C}$ ., a practically unattainable temperature. At about  $49^{\circ}\text{C}$ . there is greatest deposition of colour (.08 per cent.); then there ensues a single inflexion in the curve, which want of leisure has prevented our working out in detail; and lastly, the curve descends rapidly towards the axis of no colour, though at  $85^{\circ}\text{C}$ . it is still remote therefrom.

Our experiments have convinced us that, where an aniline colour is susceptible of dissociation, there is a positive disadvantage in using high temperatures in the dye-bath. In such cases, also, the colour should, if possible, be employed only to saturation and not in excess, in order to avoid the irregularities introduced by the latter method immediately after the point of greatest deposition.

## ON THE PRODUCTION OF AMMONIA FROM THE NITROGEN OF MINERALS.

BY GEORGE BEILBY.

THE organic origin of carbonaceous deposits of all kinds from peat at one extreme to bituminous shales at the other is generally recognised, and it is also recognised that both animal and vegetable remains have contributed towards their formation. Whatever changes have occurred in the structure and composition of these remains, involving probably the loss of a great part of their oxygen, hydrogen, and carbon, a large proportion of the nitrogen of the original structures is always found in the altered deposits. It is probable that a study of the alterations which have taken place in the constitution of these nitrogenous bodies, as they occur in the older deposits, would throw further light on the whole subject, investigators having hitherto concerned themselves chiefly with the alteration of cellulose and similar substances.

In "Watt's Dictionary" (I. 426) there is a table of analyses of certain natural bitumens, which are found to contain from 1 to 2.3 per cent. of nitrogen, thus indicating their probable organic origin. In this connection it is interesting to note that while all crude oils or naphthas, artificially prepared by the destructive distillation of carbonaceous deposits, contain nitrogen in the form of alkaloidal tars, the natural American petroleum do not contain any nitrogen. This statement is based on the results of the examination of many ship loads of crude petroleum residuum which have passed through the refinery at Oakbank Works during the last twelve years. If, therefore, these petroleum have been produced from organic deposits by a process of subterranean distillation, what has become of the organic nitrogen?

It is sufficient for the object of the present paper to point out that the more or less altered nitrogenous constituents of the older organic remains behave on dry distillation in much the same way as the original substances would have done. Animal substances such as albumen, fibrine, gelatine, and the corresponding vegetable substances, yield on distillation (1) ammonia, (2) an oil rich in alkaloidal bodies, and (3) a carbonaceous residue which contains a large proportion of the nitrogen of the original substance. When the more or less altered deposits, peat, brown coal, coal, and shale are distilled, a very similar redistribution of the nitrogen is found. Ammonia is the universally-recognised product of such distillation, but the alkaloidal tars, although the repository of a considerable portion of the original nitrogen, have not received in this respect much attention. Grouven states that peat tars contain 30 to 40 per cent. of the nitrogen of the peat, and by actual determinations I have found that coal tars contain 5 to 10 per cent., and shale oils 20 to 30 per cent. A number of the more volatile alkaloids have been examined and are well known, but when all of these have been separated, others still remain a mass of uninvestigated tar.

In the years 1871-3 I investigated the distribution of the nitrogen of bituminous shales when it is distilled for the production of paraffin oils, and found that of 100 parts of nitrogen in the original shale there is found—

As ammonia in watery distillate.....	17.0
In the oil as alkaloidal tars.....	20.4
In the residue or coke.....	62.6

The alkaloidal tars make up about one-fourth part by weight of the oily distillate. In the products of the particular shale investigated, the oil contained 1.16 per cent. of nitrogen, while the tar contained 4

per cent. A redistillation of the entire oily distillate effects a further alteration of the distribution of the nitrogen, giving ammonia in small quantity, an oil containing less nitrogen, and a coke containing nitrogen. The coke from the crude oil stills at Oakbank Works was analysed, and it consisted of two distinct forms: (a) 1in. to 2in. of hard dense coke, containing 2·8 per cent. N; (b) 10in. to 12in. of spongy pitch, containing 3·2 per cent. N. To determine approximately the redistribution of nitrogen, which takes place when the alkaloidal tars themselves are distilled, a quantity of tar which had been separated from crude shale oil by treatment with 8 per cent. of unconcentrated sulphuric acid, was neutralised with soda and distilled. Nine fractions were taken off. The first, containing

water and the most volatile alkaloids, was unfortunately lost, but the remaining eight, together with the residue, were weighed and analysed by Grouven's method.

Fraction	Grammes	Contained per cent. N.
2	100	3·54
3	100	3·37
4	60	3·35
5	110	3·24
6	60	3·17
7	80	3·54
8	50	3·35
9	50	3·54
Residue	390	4·00

Before the final fraction came off the still was at a temperature little short of redness. This experiment clearly shows the comparative stability of these nitrogenous substances, the least volatile portion containing the largest proportion of nitrogen, even after exposure to a red heat. This result was confirmed, as far as the residue was concerned, by a determination of the

nitrogen in the residue from the distillation of the alkaloidal tars in the works in a 5-ton still: it contained 4·1 per cent. of nitrogen.

In the distillation of shale the products come off in regular order as to boiling point and purity: First, hydrocarbon gas; next, colourless oil; then a yellow oil containing solid paraffins; and finally brown tarry oils, which consist largely of alkaloidal substances. Now, just as in the distillation of the alkaloids of the

FIG. 2.

Scale  $\frac{1}{8}$  inch to 1 foot

oil, less and less volatile matter comes off, until a residue non-volatile even at a red heat is left behind, so I believe that when shale or coal is distilled only the more volatile alkaloids come off, and the coke or residue still contains the less volatile or pitchy nitrogenous bodies. The accompanying diagram will further explain this.

DISTILLATE.	RESIDUE.
Alkaloids: $C_3H_5N$ to $C_{11}H_7N$ (?)	Higher alkaloids, or substances like carbazol, etc.
Hydrocarbons: $C_2H_4$ } to { $C_{27}H_{56}$ $C_2H_6$ } { $C_{27}H_{54}$ (?)	

It seems probable that there are series of carbon-hydrogen-nitrogen compounds of unbroken continuity from the volatile piccoline, pyridine, etc., up to

pitchy or coke-like substances. Though this pitch probably contains a considerable percentage of free carbon, yet its high percentage of nitrogen (4.1 per cent.) indicates that it must be largely composed of nitrogen-carbon-hydrogen compounds. Carbazol ( $C_{12}H_9N$ ) contains 8.38 per cent., and phenyl-naphthyl-carbazol ( $C_{16}H_{11}N$ ) contains 6.45 per cent. Both of these have been obtained from anthracene-residues, and are eminently stable substances of high melting and boiling points. It seems likely that an examination of coke, pitch, and alkaloidal residues would lead to the discovery of these or similar substances among their constituents. As time permits, I hope to extend my investigations in this direction. Mr. J. O. Morrison, in carrying out test distillations on a very small scale in the laboratory—20 to 30 grms. being heated very gradually to a good red heat—has found that the quantity of ammonia obtained simply by the action of heat in this way is double what could have been obtained on a manufacturing scale by simple dry distillation. The particular shale already referred to, distilled in the way described, gives the following results:—

	Per cent.
Total nitrogen.....	0.70
	Per cent.
Of which there was obtained as $NH_3$ ....	0.23
Of which there was obtained as alkaloids in distillate.....	0.14
Of which there was obtained in the coke.....	0.32
	— 0.69
Loss.....	0.01
Taking the total nitrogen of the shale as 100 we have—	
As ammonia in watery distillate.....	32.8
As alkaloids in oil.....	20.0
In the residue.....	45.7
	98.5
Loss.....	1.5
	100.0

In this case it is probable that the gradual but very thorough heating of the coke has brought about a decomposition of the residual alkaloids with a maximum production of ammonia and a minimum of free nitrogen, the large percentage of porous ash—about 90 per cent. of the whole coke favouring this decomposition. It is evident that the same heat applied to large pieces of shale might have an altogether different effect, as the gas from the interior would have to pass out through a considerable thickness of hot earthy residue, and be to a great extent decomposed. This theory would explain the well-marked difference in the behaviour of the nitrogen of pitchy minerals, such as cannel and shales. I have found that the residual cokes of the former stand a very high temperature, even a light-red heat, without dissipation of their nitrogen, while the latter are extremely sensitive to high heats, and would part with large quantities of free nitrogen at such temperatures. The investigations of Dr. H. Grouven on the conversion of combined nitrogen into ammonia have been very completely described by him (*Versuchstationen* J. 28, 343). By his method the substance is burnt in a large excess of steam, the alkaloidal vapours being conducted over or through a highly-porous “contact substance,” in which the necessary conditions of time and contact are supplied, so that they are decomposed into  $CO$ ,  $CO_2$ , and  $NH_3$ . His analytical apparatus has been in use in the laboratory at Oakbank for four or five months, and a large number of the nitrogen determinations recorded in this paper were performed with it. Three

determinations of the nitrogen in a shale by the two methods gave the following results:—

Soda-lime. Per cent.	Grouven. Per cent.
0.70 .....	0.70
0.75 .....	0.70
0.69 .....	0.63

The determination of nitrogen in a coal gave the following results:—

Soda-lime. Per cent.	Grouven. Per cent.
2.25 .....	2.20
2.20 .....	2.30

In both Grouven's and the soda-lime process provision is made for the separate treatment of the more or less volatile portions of the substances to be analysed. In the former (Grouven's) the alkaloidal vapours are decomposed directly by steam, the chief function of the contact substance being to keep the vapours and steam in contact at a suitable temperature; in the latter process the red-hot soda-lime in the fore part of the tube supplies the elements of water, and to a certain extent provides for contact. In the first process the non-volatile nitrogenous substances are burnt by the direct action of steam alone; in the second the elements of water are supplied by the caustic soda. But as the soda will not part with these elements unless the carbon is in intimate contact with it, this has to be insured by very careful grinding of the substance, and very intimate mixture of it with the soda-lime. Operators who have been at pains to determine the nitrogen in coals and shales must have noticed how very frequently the ignited soda-lime, on subsequent examination, shows traces of unburnt carbon, and just so surely as this is the case will the results obtained be low. When once the art of managing the heats in Grouven's apparatus has been mastered this difficulty is completely overcome; the substance, without preliminary grinding or treatment of any kind, can be completely burnt to ash. Also, by proper regulation of the heat on the contact substance, the escape of undecomposed alkaloids can be entirely avoided.

An examination of the tables of coal analyses published in standard works has convinced me that these determinations must in many instances have been very imperfectly performed, as the averages brought out are much below the truth, as far as I have been able to ascertain it, by the careful determination of the nitrogen in specimens from many different localities. It has occurred to me that a valuable modification of the soda-lime process would be the introduction into the back end of the tube of some substance, which at a moderate heat would give off water which would not only sweep out the tube, as the carbonic acid from bicarbonate of soda at present does, but in addition would supply the elements of water to the ignited mixture of soda lime and substance in case that mixture had not been intimate enough to complete the decomposition. Hydrated oxide or sulphate of calcium would serve the purpose admirably. Any treatment of the subject of this paper would be incomplete without something more than a passing reference to Mr. R. Tervet's researches (this journal, 2, 445) on the influence of hydrogen in favouring the production of ammonia from nitrogenous substances. These researches form a most important and original contribution to the knowledge of the subject. Having in July, 1883, been favoured with an early account of Mr. Tervet's experiments, I arranged, with his consent, to carry out an independent series of experiments bearing on the subject. The results of these experiments were chiefly confirmatory of Mr. Tervet's own conclusions, but had also a bearing on the line of investigation followed by Grouven, Young, and myself. They are therefore reproduced

here. The substances experimented with were coal, shale-coke, and peat. The apparatus used was an iron tube of  $\frac{1}{2}$  in. bore, heated in a gas combustion furnace. The gases passed through the tube were supplied from a graduated gasholder, and were thoroughly dried by passing through a complete set of chloride of calcium tubes. The ammonia was caught in the standard acid, in ordinary nitrogen bulbs. The coal used was the soft or partially-caking portion of the Lanarkshire main coal. Analysed both by the soda-lime and Grouven's methods it gave 2.3 per cent. of nitrogen. Mr. Tervet has expressed the ammonia obtained as pounds of sulphate per ton of coal. Stated in this way the coal used contained nitrogen equal to 2.43lb. of sulphate of ammonia per ton.

ABSTRACT OF EXPERIMENT 1.		Lb. per ton.
Distillation for 25m. ammonia as sulphate.....		27.70

In experiments 3, 4, and 5, peat and shale cokes

FIG. 3.

Scale  $\frac{1}{8}$  inch to 1 foot.

The coal was roughly powdered and made up in paper cartridges, which could be slipped easily into the iron tube. Each cartridge contained 250 grains (10.6grms.), and measured about 7in. in length. The cartridge having been slipped into the tube, the burners were lighted at the front end of the tube, and the heat was then carried back along the tube, just so quickly as to keep up a brisk evolution of gas. When the evolution of gas began to fall off rapidly, a small current of gas from the holder was turned on for one or two minutes, to sweep out the vapours. The nitrogen bulb was then replaced by a fresh one, and the regular stream of gas turned on, the bulb being replaced by a fresh one, whenever it was necessary to determine the ammonia.

were used, but as they were not carried beyond the stage of the two preceding experiments they need not be reproduced here. It is sufficient to note that shale coke parts with comparatively little of its nitrogen under the influence of hydrogen.

		11.35

\* The coke at this stage weighed 147.5 grains, equal to 59 per cent. of coal. It was again weighed after the steam had been passed over it, and was found practically unaltered, showing that the temperature used had been below the incinerating point.

In none of the preceding experiments had the ammonia-yielding property of the coke been perfectly exhausted, hydrogen which had passed over it still turned turmeric brown. The seventh experiment was carried out to exhaustion, and the nitrogen of the residual coke determined by soda-lime analysis. At the stage marked \* the coke was finely powdered, to insure free access of the hydrogen. Throughout all of these experiments the heat of the combustion tube was very uniform: it showed as a well-marked blood red in diffused daylight.

## ABSTRACT OF EXPERIMENT 7.

One cartridge, 7in. long, 1in. diameter.		Total

Left in coke by soda-lime determination (0.82) .....		50.62lb. = 20.83
Lost as free N .....		125.31lb. = 51.57
Total N of original coal=ammonia as sulphate .....		117.66lb. = 18.43
Total N of original coal=ammonia as sulphate .....		213.00lb. = 100.00

The coke (containing 0.82 per cent. N) was heated to whiteness in the laboratory in an iron crucible, and was afterwards analysed by soda lime, and gave N=0.4 per cent. It was again heated in a fire-clay crucible in the smith's fire, and kept at a bright white-heat for several hours. Analysed by soda lime it gave N=0.25 per cent. Treated with hydrogen at a red heat at this stage it gave up no ammonia. These latter results indicate the wonderful stability of some of the nitrogenous constituents of the coke. As Mr. Tervet is still following out his investigations on this subject, I refrain from further comment on these experiments. I have devoted much time and attention during the last twelve years to the solution of the problem, how more economically to dispose of the nitrogen of shales and coals. Both alone and also in association with Mr. William Young many experimental investigations have been carried out, some of the practical results of which have been embodied in manufacturing processes now commercially established. Certain of these have been described elsewhere (*Journal of Gas Lighting* 40, 257, and 42, 317, *Trans. M. Inst. S.* 5, 158), and need, therefore, be only very generally noticed here. For many years steam has been passed through shale retorts during the distillation, and has been found to increase the yield of ammonia to a considerable amount beyond what had been obtained by simple dry distillation. In 1873, at Magdalen Bridge Works, Mr. Young and the writer proved that the same effect was produced if steam was passed through the red-hot residue after the oil distillation was completed. This system was afterwards applied to a bench of Young's patent retorts in Oakbank Works. But though steam was used in these ways with distinct advantages to the yield of ammonia, the distribution of the nitrogen in the products was still unsatisfactory. The results of this treatment with the shale, already referred to, gave the following distribution, again taking the total nitrogen of the shale as 100—

As ammonia in the watery distillate .....	24.2
In the oil as alkaloidal tars .....	20.1
In the residue or coke .....	55.3

As the nitrogen of the coke could be obtained as ammonia by ignition of the coke with soda lime, it occurred to us that if the coke were ignited in steam

the same effect should be produced. This was proved to be the case by actual experiment. In 1881 a single retort was erected at Oakbank, in which shale was first distilled at a low-red heat in an iron retort, and was afterwards subjected to the action of steam at a bright-red heat in a fire-clay retort. The fixed carbon of the residue was burned away, and the nitrogen came off as ammonia. In this retort almost theoretical results were obtained, the exhausted residue or ash containing only 4.9 per cent. of the nitrogen of the shale, while the remainder was found in the distillate. Stating these results as before, we have—

As ammonia in the watery distillate .....	74.3
In the oil as alkaloidal tars .....	20.1
In the residue or coke .....	4.9

With the exercise of appropriate care it was found possible to repeat these results at will, but a serious difficulty was experienced in working certain shales, owing to the fusibility of the ash after the removal from it of the fixed carbon. Our earlier retorts were designed of small diameter and capacity, to insure the ready access of heat to the centre of the mass of shale, and were worked at a temperature little, if at all, short of the melting or softening point of the ash. We have more recently found it better to make the retorts of much larger size, so that the shale may remain under the influence of heat and steam for a longer time, and at a somewhat lower temperature. In this way much of the difficulty which arises from the melting and sticking of the ash is avoided. The shale retorts shown in cross section in Fig. 1 were erected at Pentland Works a year and a half ago, and have given very excellent results during that time. The shale is charged into the hopper A by doors on the top. It is here heated up by the hot gases passing up from the retorts below, and as the whole column of material is moved down by the removal of a part of the spent ash at the bottom, the shale passes in succession through the iron retorts A<sup>1</sup> and the fire-brick ovens A<sup>2</sup>. In the former it parts with its hydrocarbon oils and paraffin, and in the latter the carbon is more or less completely burned away in steam, producing water gas and ammonia. The earlier forms of these retorts were heated by open furnaces, and the proper regulation of temperature was very difficult. In the retorts at Pentland the furnaces are replaced by coal retorts, shown in cross section in Fig. 2. In these combined retorts and gas producers coal is first distilled, then partly burned in steam, and finally completely reduced to ash by the regulated admission of air. At each stage heating gas is produced, and by suitable appliances is burned in the chambers in which the retorts are set. By this arrangement the full advantages of gas firing are gained, and at the same time a large yield of by-products is obtained from the fuel.

In 1882 we discovered that a certain proportion of air might be mixed with the steam used for the burning of nitrogenous carbon, without seriously reducing the yield of ammonia. The principal advantage of such a use of air is that a certain amount of heat is thereby generated within the retort, and consequently less has to be supplied from the outside, and a lower working heat can therefore be maintained. This use of air, if properly regulated, does not sacrifice much of the nitrogen of the coke, and we have found in certain cases that the increased volume of hot gas from the lower retort, in which the carbon is being consumed, tends to carry on the distillation of the shale in the upper retort, under conditions very favourable to the production of the most valuable hydrocarbons—the solid paraffins. In January, 1883, a set of retorts, worked alternately with steam alone and with steam and air, showed with the latter a gain of oil yield of about 10 per cent.,

and of solid paraffins of 25 per cent.—that is, a shale which with steam alone gave 30 gallons per ton of an oil containing  $10\frac{1}{2}$  per cent. of solid paraffins, with steam and air gave 33 gallons per ton of an oil containing  $12\frac{1}{2}$  per cent. of solid paraffins. The steam used in both cases gave about 72 gallons of condensed water per ton of shale. In other sets of retorts a similar gain of oil and paraffins has been obtained by the use of a sufficiently large volume of steam alone, 120 to 150 gallons of water being condensed per ton. It is at present an open question which of these methods will in the long run give the most economical results. The advantages of air are, its cheapness as compared with steam, the internal heat which it supplies, and a certain crispness which it gives to the spent shale, which permits

long we shall recover the nitrogen of the alkaloidal tars by the use of the beautifully-contrived ammonium ovens of Dr. Grouven. A description of his apparatus, comprising incinerating and ammonium ovens and ammonia soda plant, would alone furnish matter for a long paper, and cannot be entered into on this occasion. The interest of a process confined to a comparatively limited industry like the oil trade of Scotland cannot for a moment be compared with that attaching to its application to the larger industry of fuel gas making. A good deal of our attention has been turned on the application of the Grouven-Young-Beilby process to the treatment of coal for the production of heating gas and ammonia. When it is remembered that the process involves the decomposition of water by carbon, the oxidation of

FIG 4

Scale  $\frac{1}{2}$  inch to 1 foot.

of its being withdrawn from the retorts very easily. The disadvantage of the use of air is the increased volume of incondensable gas which has to be handled, largely consisting, as it does, of the useless nitrogen of the air. Not merely does this extra volume involve increased exhausting and condensing plant, but it carries forward with it an excessive quantity of light naphtha which can only be recovered by the use of very extensive oil scrubbers. Only a prolonged working experience will enable us to decide as to the economical limits of the use of air in shale distillation. The thermo-chemical and economic aspect of its use in the treatment of coal will be referred to later.

The process so far described has only had reference to the recovery of the nitrogen of the residual coke from shale distillation, but it is probable that before

the latter to carbonic oxide and carbonic acid, and the setting free of hydrogen, its suitability as a means of producing heating gas is evident, as far, at least, as the quality of the gas is concerned. When it is further pointed out that by this process from 60 to 70 per cent. of the nitrogen of the coal can be obtained as ammonia, it must be admitted that it opens up a distinct possibility of an economical production of heating gas. Between the theoretically perfect process—so well illustrated by the analytical apparatus of Grouven—and its economical realisation on a large scale there are many steps to be taken. The fundamental difficulty of the transition is simply stated. It is this: The temperature at which carbon freely decomposes water is considerably above that at which ammonia is decomposed. The former tempera-

ture may be taken as not lower than 1,100° to 1,200° C. The recently-published results of Drs. Ramsay and Young (*Chem. Soc. Journ.* 256—88,) show that under favourable circumstances (contact surface and time) decomposition begins a little below 500°. It is evident, therefore, that favourable circumstances and a temperature of 1,100° to 1,200° will completely decompose ammonia. Clearly, then, the ammonia could only be saved by making the conditions of the process as unfavourable as possible to its decomposition. It was necessary therefore to reduce the chances of contact of the ammonia molecules with surfaces at the decomposing temperature. This could best be done by diluting the ammonia gas with a large volume of a neutral gas consequently Grouven provides in his analytical to apparatus the use of a quantity of steam equal to 20 to 30 times the weight of the substance to be analysed. It is evident that such a proportion could never be economically used on a large scale. Anything like 20 tons of steam for 1 ton of coal would place the process outside of the practical region at once. In our earlier laboratory experiments we found that about 60 per cent. of the total nitrogen could be obtained as ammonia by the use of 4 to 5 parts of steam

tar vapours are completely decomposed. Only a pitchy dust is deposited in the long dust pipes and mains. The dross used in these retorts contains nitrogen equal to 165lb. to 170lb. of sulphate of ammonia per ton. Week after week since the beginning of the year we have obtained yields ranging from 90lb. to 125lb. of sulphate per ton, or say 60 to 70 per cent. of the total nitrogen. The quantity of steam used has varied from 2,500lb. to 3,500lb. per ton of dross, equal to 250 to 350 gallons, so that the proportions of coal to steam now stand—1 coal to 1½ steam. The composition of the incondensable gas varies somewhat, according to heats, air supply, etc. A sample collected on the 5th inst., and analysed, showed the following composition (by volume):—

CO <sub>2</sub> .....	16·6
CO.....	8·1
CH <sub>4</sub> .....	2·3
H <sub>2</sub> .....	28·6
N <sub>2</sub> .....	44·4
	100·0

This indicates a rather excessive air supply, as we aim generally at a consumption of one half of the fixed carbon with air, the other half with steam.

TABLE I.

to 1 of coal. Then it occurred to us that air might be made to take the place of a part of the steam, and experiments proved the correctness of the surmise. Thereafter our aim was to devise a practical apparatus in which the conditions most favourable to the preservation of the ammonia could be economically maintained. Figs. 3 and 4 show two cross sections of a bench of coal retorts, which have been at work at Oakbank since October last. In the upper part of the retort the dross or small coal, which is fed into the top by screw feeders, is distilled, the tar vapours, together with the steam, passing down through red-hot coke, are decomposed into permanent gas and ammonia, and pass away by the exit pipe situated about the middle of the retort. The coke passing down into the lower half of the retort is burned in a mixture of steam and air, the resulting gases passing upwards and away by the centre exit pipe. The united gases from the upper and under retorts are drawn through condensers and scrubbers, where the ammonia is separated and recovered. When the heats are properly regulated the

With such an admission of air the composition of the gas would probably be:—

CO <sub>2</sub> .....	21·32
CO.....	10·72
CH <sub>4</sub> (etc.) .....	nil
H <sub>2</sub> .....	37·19
N.....	30·77
	100·00

Elsewhere (*Trans. M. I. Scotland*, 5, 178) I have published a series of tables showing the thermal values of the reactions between the elements of an average coal and steam in excess. The accompanying Tables, I., II., and III., show these reactions and values when 50 per cent. of the carbon is burned with air and 50 per cent. with steam. The units used are Centigrade degree-pounds. The thermal values of the equation are based on Thomson's numbers:—

[C—O]=96,060.  
[C—O]=29,290.  
[CO—O]=67,670.  
[H<sub>2</sub>—O]=58,069, at 100°.

The available published figures for the loss of heat through the brickwork of retort benches are so mani-

festly inaccurate that new determinations of the conducting power of fire-brick were made. The method employed was similar to that used by Peclet (*Ann. Ch. Phys* 3, ii., 107), but instead of using the small differences of temperature to which one is restricted when water is used on both sides of the conducting medium, large differences, of  $260^{\circ}$  to  $300^{\circ}$  C., were maintained by the use of a lead-tin heating bath. A detailed description of these experiments would be out of place here, but the general result showed that one square foot of fire-brick lin. thick passed 6.59 heat units per hour for each degree of difference between the temperatures of the two sides of the diaphragm. From this it was calculated that the loss over the whole apparatus amounted to about 2,000,000 units per ton of coal treated. From an examination of Table II. it is seen that 6,961,362

units have to be supplied for the gasification of one ton of coal. Taking up the several items *a*, *b*, *c*, *d*, *e*, and *f*, it is found that (*a*) is provided by waste heat from the later stages, (*b*) is expended in boilers or steam generators or supplied by waste heat, (*c*) and (*d*), minus quantities, are met by (*f*), leaving only 1,511,292 units to be supplied otherwise, (*e*) has to be provided for in the apparatus, (*c* + *d* + *e* - *f*) may be provided in either of two ways, or by a combination of the two—first, by pre-heating the steam and air, or secondly by passing in heat through the walls of the retorts. The first has been adopted by Grouven in his most recent incinerating ovens. The mixture of steam and air is raised to a white heat by means of hot blast ovens or stoves on the exchanging principle, and the hot blast is forced through the peat or coal in solidly-built ovens. The second plan has been adopted primarily in the retorts shown in Figs. 1, 2, 3, and 4, supplemented, however, by the first. It seems

to us, in the light of our present knowledge, that the combined system is the more economical, but an extended experience may lead to a change of opinion. As to the practical heating results obtained—the small set of retorts at Oakbank are consuming in all 4 tons of coal per day, and in return produce 90lb. to 100lb. of sulphate of ammonia per ton, and heating gas sufficient to fire 32 shale retorts, which were formerly heated by two ordinary furnaces, consuming each 2 tons of coal per day. While these data are not sufficiently full to enable one to frame a *final* estimate of the practical gains and losses of heat, they do give a very clear indication that practical results are being realised which correspond very fairly with theoretical calculations. For the sake of simplicity this apparatus was not provided with any adequate heat recuperators, by the use of which, in future, we may expect to effect great economy of heat.

In concluding this paper it gives me much pleasure to acknowledge my indebtedness to my friends and colleagues, Messrs. G. D. H. Mitchell, E. H. Ronalds, and J. O. Morrison, who have performed numerous analyses and laboratory experiments in connection with the subjects treated of, and to Messrs. W. A. Bryson and G. J. Hamlen, who have superintended and carried out experimental operations in the works, at no small sacrifice of their personal leisure and comfort.

## DISCUSSION.

The CHAIRMAN: I am sure we are all deeply indebted to Mr. Beilby for this very remarkable paper, for he must have spent a great amount of labour upon it. The apparatus and diagrams which we see before us are extremely ingenious, and realise all that has been predicted for the process. There must be several members present who wish to say something on this very important paper, and we shall be glad to hear their remarks.

Mr. R. R. TATLOCK: I do not know that I can say anything that will add to the interest of this very valuable paper, and what little I have got to say is entirely from an economical point of view. I must confess that when I first heard of Mr. Beilby's improvements it occurred to me that there was no need for incurring expense for steam and outside heating in order to obtain ammonia, there being so much of it wasted in this country by iron manufacturers and others who had it absolutely for nothing. In the blast furnaces of Scotland, working with raw coals in Scotland, and in the comparatively few working with raw coal in England, we have a waste of ammonia amounting to 30,000 tons per annum. That ammonia can be had for the extracting, for the mere condensing or fixing by means of chemicals, which can be done, even at present low prices, with a manufacturer's profit of at least 100 per cent. These processes have not been carried out to any great extent, even up to the present time. In addition to that, there is a large quantity of ammonia, as we all know, wasted in the present processes of coking coal, that up to the present moment has only been very partially recovered. We cannot say that that enormous amount can be got merely for the lifting, because it seems that in order to recover it the ovens must practically be rebuilt before the best results can be obtained, but looking to the enormous consumption of other nitrogenous materials, it is quite plain that there is plenty of room for all the processes. There were last year about half a million tons of nitrate of soda consumed over the entire world. If we take, as I have said, the waste of 30,000 tons going on at present—I cannot say how much from gas producers, and that must also be considerable—and perhaps 200,000 tons which could be recovered from coking ovens, there is still a large

margin, and the question is whether this process of Mr. Beilby's, where extra expense is involved, will pay at the present rates—which are likely to be continued for a length of time, probably for many years. Since it is not probable that nitrate of soda will be brought into European ports very much cheaper than at present, I think there is a prospect of plenty of room for the ammonia that can be produced by these means, over and above what is absolutely wasted, so that even should these wastes be utilised, there will still be plenty of outlet for ammonia manufactured in this way, and if Mr. Beilby can satisfy us that it is an economical one, with sulphate of ammonia at present prices, or even 25 per cent. lower, there is no reason why it should not be adopted with success, even considering that it does cost money to produce it, and has to contend with ammonia already produced, and going to waste, as well as with nitrate of soda.

The CHAIRMAN: I was struck with the large proportion of nitrogen that appeared to be obtained—40 per cent., I think.

Mr. BEILBY: That is on the authority of Dr. Grouven. He asserts that 30 to 40 per cent. comes away in that form. From my own examination of peat I should say that this is probably an over-statement, but in certain shales I have found fully 40 per cent. of the original nitrogen in the oily distillate.

Dr. WALLACE: The tenacity with which nitrogen is retained by carbon, as described in Mr. Beilby's paper, is well illustrated by the case of the animal charcoal used in sugar refineries. The new charcoal, containing about 10 per cent. of carbonaceous matter, usually described as carbon, has from 1·2 to 1·5 per cent. of nitrogen, equal to 12 to 15 per cent. of the weight of carbonaceous matter. Every time this charcoal is used in the refining process it is washed, dried, and reburnt, and on each occasion there is a loss of nitrogen, somewhat considerable during the first few times but afterwards very small. Even after 200 reburnings, occupying three to four years, the proportion of nitrogen which remains constitutes 2 to 3 per cent. of the weight of the carbonaceous matter. Formerly it was the custom in some sugar-houses to draw the charcoal red hot from the kilns, and extinguish it with water, when invariably ammonia was given off along with the steam, the quantity being very considerable when the charcoal was comparatively new. The subject which Mr. Beilby has brought before us is one of great importance, and, as Mr. Tatlock has said, there is no doubt about the process itself, but experience is required to show whether it is more economical than methods in use in oilworks of older construction.

Mr. TERVET: I have much pleasure in expressing the satisfaction with which I have listened to Mr. Beilby's paper, which I consider a most valuable contribution to the subject, and one in which I have taken a deep interest. In acknowledging the honour which Mr. Beilby has done me in referring to my own investigations, I have to observe that his results differ somewhat from those obtained by myself; and I believe that these differences arise from his not having passed a sufficient volume of hydrogen through the retort. Mr. Beilby said, I think, that during the first 240 minutes one cubic foot of hydrogen was passed, and during the second 240 minutes three-quarters of a cubic foot. In my own experiments, during one-half that time, over a hundred times that volume of hydrogen would be passed, and under slight pressure. In describing my experiments I made special reference to the importance of having a very large excess of hydrogen in circulation, therefore I think that the small volume of hydrogen is the cause of the discrepancies which exist between the results obtained by Mr. Beilby and my own. I have also to say that

I can fully bear out the results of Mr. Beilby's investigations on the alkaloidal bodies obtained from crude shale oils. It is a very interesting fact that the proportion of nitrogen should be distributed almost uniformly through the whole series of a fractional analysis of the distilled alkaloids.

Mr. T. L. PATERSON: I have always found that new animal charcoal contains a large proportion of nitrogen, that leaves it after the charcoal has been used, and yet after a great many years it still contains portions of nitrogen. If Mr. Beilby had made any experiments with the view to determine the nature of the alkaloids remaining in the coke from the distillation of shale, it might throw considerable light upon the presence of nitrogen in the charcoal.

Mr. BEILBY: I have not direct proof, the evidence is only circumstantial.

Mr. PATERSON: I think your hypothesis is a very probable one, but I just wanted to know if you had made any such experiment.

—————♦♦♦♦♦—————

*Meeting held on Thursday, March 27th, 1884.*

MR. ED. C. C. STANFORD IN THE CHAIR.

# ON THE DISTRIBUTION AND CONDENSATION OF THE GASES IN THE LEADEN CHAMBER.

BY J. MACTEAR, F.C.S.

It is somewhat surprising that so little work has been done towards the elucidation of the relative distribution and condensation of the gases in the various parts of the leaden chambers employed in the manufacture of vitriol. The most complete series of experiments, of which details have been published, are those of the late Mr. H. A. Smith, who made a considerable number of experiments upon the subject both in the laboratory and in the chambers themselves. The result of his experiments led him to believe that the chief portion of the acid was produced and condensed close to the surface of the acid already formed in the chambers. He made his experiments on a chamber 140ft. long by 30ft. high and 25ft. wide, and he divided the chamber into lengths of 10ft., and into levels or zones of 3ft. and 15ft. from the floor. I have taken out his figures and have put them into the form of diagrams, which show the relative proportions existing at the various points of the chamber of sulphurous acid, sulphuric acid, and nitric acid. One of the chief points brought out by thus placing his figures in diagrammatic form is, that we can see in a very marked degree the effect

of the introduction of the steam, which has reduced largely the amount of sulphurous acid at the points where it enters the chamber, there being a corresponding increase in the amount of the sulphuric acid. Taking, now, Mr. Smith's results in figures, we find that there are great variations and irregularities, due, I believe,

simultaneously, as would be absolutely necessary to obtain accurate results.

In order that we may have some idea of the conditions under which the chambers are worked as regards

the distribution in each chamber of the various gases, let us take the case of a set of sulphuric acid chambers, six in number, burning pyrites, and assume that the gases are led, first, through a Glover tower, and then through the chambers, one after another, in sequence, finally passing through a Gay-Lussac tower. Let us also assume that the nitrous compounds present in the chamber are = 10 per cent. of nitrate of soda on the sulphur burned; that these compounds are calculated as existing as N<sub>2</sub>O<sub>4</sub>; that the residual gases are allowed to escape with 10.4 per cent.\* of oxygen, .33 grains per cubic foot nitrous compounds calculated as nitrate of soda, and 5 per cent. of the original sulphur escaping as SO<sub>2</sub>. Neglecting the watery vapour, which it is very difficult to calculate, Table II. shows the relative composition of the gases entering the Glover tower, and as they pass from chamber to chamber in series. The difference between the gases entering the first chamber and those entering the second

\* This figure is merely taken for convenience of calculation. Oxygen varies much in the different cases. A fair average might be taken as 7 to 7½ per cent. estimated in the exit gases after passing all condensing towers, etc. With old or leaky chambers it often amounts to as much as 11 per cent.

chamber show at a glance the amount of condensation which has taken place. A more striking way, however, of showing this is, perhaps, by the diagram, in which the large square represents the total chamber space and the lower shaded square represents the proportionate bulk of sulphurous acid in the various chambers as the gases pass through. The upper shaded squares show the nitrous compounds, as  $\text{NO}_2$ , in the same way. The results from which these figures were calculated were obtained by a long series of determinations of the acid condensed in the various chambers, and which were made with great care, with the special object in view of finding out the relative amounts condensed in the various chambers. Table III. shows comparative chamber condensation, and gives the results for one week, during which the loss of acid escaping was estimated by my continuous testing arrangement, and for the week in question it amounted to 1.149 per cent.  $\text{H}_2\text{SO}_4$  of sulphur burned. Table IV. gives details of the relative condensation in a number of series of chambers of varying construction and size. We have now some idea of the composition of the

attached to the sides of the chamber, and the results led him to conclude that Smith's conclusions were not trustworthy, and that on an average about 80 per cent. of the total acid produced was formed in the upper portion of the chamber within three or four feet from the roof. I carried out a long series of experiments upon a set of chambers, divided by curtains into six sections, as shown upon the plans, the curtains having their openings alternately at the top and bottom. These chambers were fitted up with a series of sampling apparatus, consisting of leaden trays exactly one foot square each, and communicating with the outside of the chambers by a lead pipe, enabling the quantity of acid to be measured at stated periods. These trays were supported at heights of 3ft. 9in., 7ft. 4in., and 11ft. 3in. above the bottom of the chamber, and there was also, in addition, the usual side drip pocket upon the chamber wall.

In the first series of experiments the trays were left open and uncovered, and the daily yield of acid which had condensed upon these trays

DIAGRAM 1.—SULPHUROUS ACID.

DIAGRAM 2.—SULPHURIC ACID.

DIAGRAM 3.—NITRIC ACID.

DIAGRAM 4.

gases in the various chambers of the series, and also the relative proportion of acid condensed in each chamber. We have now to consider the question as to zone or level of the chamber, in which the formation of the acid chiefly takes place. Mr. Smith concluded from his experimental results that the formation of acid was most active in the lower portion of the chamber, and from this cause he advocated the building of chambers of comparatively low height, but of considerable length. Mr. Smith's results, however, as shown by the figures which he gives, are somewhat misleading, owing to the method adopted for taking the sample, and his conclusion I believe to be quite an erroneous one. Some investigations have been made, I believe, by Mr. Hasenclever on the amount of acid formed upon trays suspended at various points in the chamber. I have not been able to obtain the details of these experiments, but Mr. Deacon, who also worked upon this subject, kindly gave me the results of his experience. His experiments were carried out by a series of gauges

was carefully recorded for some months, both as to quantity and strength. There was considerable irregularity observed, and this was found to be caused by the lead of the roof wrinkling, from its expansion and contraction, the acid condensing upon the roof lead dripping from these points or projections of the lead. Any change in the temperature of the air caused these wrinkles to alter their form, so that at one time a considerable quantity of acid might be formed and fall into the trays, while at another time this acid might be directed clear of them by one of these wrinkles of the lead. In order to avoid this source of irregularity I had covers arranged, hanging in such a way over the trays as to prevent any drip from the roof getting into them, and these covers were made also in such a way that they could be raised or lowered, as required. A set of results was obtained in the one case with the covers close to the roof of the chamber, and in the other with the covers lowered so as to include exactly one cubic foot of space between the cover and the tray. Taking the highest tray as

yielding 100 parts of acid, the amounts are shown in Table V., which were obtained in the same time by the middle and bottom trays. Reducing the figures in Table V. to the basis of 100 of OV made in each chamber, as found by the gauges, we have the averages shown in Table VI. The proportion of acid made is shown also in this table.

In the next series of experiments the trays were covered, the covers being kept close to the roof of the chamber, so as to leave free circulation of the gases over the trays. Table VII. gives the results. The quantity of acid made in each chamber is also given in this table.

Another series of experiments was made with the covers lowered, so that exactly one cubic foot of space was enclosed between the cover and the tray, with the view of determining the relation as to formation of acid in an equal chamber space at the different levels in the chamber. The results are given in Table IX. Reducing these figures to the basis of 100 parts OV in each chamber, as found by the gauges, as in the previous cases, we have the results found in Table X.

If we now take these various results, and arrange them side by side, as in the tables, we shall find that apparently the same amount of acid has been obtained from each set of trays. As each of the gauged trays had a different height or column of chamber gases between it and the roof, one would naturally expect that the lower trays would give an increased yield of acid corresponding to the amount of space above it, but this has not been so.

If we suppose the chambers to be divided into three zones or levels between (1) the roof and the top tray, (2) the top and the middle tray, (3) the middle and

TABLE XI.

Percentage of Acid made in each Tray.	19 Weeks' Average. No Covers Used.	Weekly Averages. Covers Used Close to Roof of Chamber.		Weekly Averages. Covers Used at 1 ft. above Trays.
		a	b

Bottom tray..	33	33	31	33

bottom tray, and designate the yields obtained from these as A, B, C, thus we would have

Upper zone = A

Middle zone = A + B

Bottom zone = A + B + C

but as we have found that A is = A + B, and also = A + B + C, it is evident that B and C can have no value, and that, so far as these results are concerned, no acid has been formed in the middle and bottom zone. To try and make this result more clear, a number of analyses of the gases of one of the chambers was made, and the following figures were obtained :—

## TOP ZONE.

SO <sub>2</sub> grms. per litre.....	126 as SO <sub>2</sub>
SO <sub>2</sub> grms. per litre. Total.....	159 as SO <sub>2</sub>
Per cent. existing as SO <sub>2</sub> .....	21 of total
Per cent. oxygen after absorption of acids	10.7
Per cent. oxygen after oxidising SO <sub>2</sub> .....	9.0

## MIDDLE ZONE.

SO <sub>2</sub> grms. per litre.....	112 as SO <sub>2</sub>
SO <sub>2</sub> grms. per litre. Total.....	159 as SO <sub>2</sub>
Per cent. existing as SO <sub>2</sub> .....	26 of total
Per cent. oxygen after absorption of acids	10.9
Per cent. oxygen after oxidising SO <sub>2</sub> .....	9.3

## BOTTOM ZONE.

SO <sub>2</sub> grms. per litre.....	108 as SO <sub>2</sub>
SO <sub>2</sub> grms. per litre. Total.....	161 as SO <sub>2</sub>
Per cent. existing as SO <sub>2</sub> .....	33 of total
Per cent. oxygen after absorption of acids	10.9
Per cent. oxygen after oxidising SO <sub>2</sub> .....	9.3

Extracting these figures again, we have :—

	Total as SO <sub>2</sub>	as SO <sub>2</sub>	as SO <sub>2</sub>	% SO <sub>2</sub> made in
Top .....	100	100	100	63
Middle....	96	89	124	15
Bottom... 101	86	157	.....	22
				100

and, as the final result, we find from these analyses 63 per cent. of the sulphuric acid actually formed has been in the top portion of this chamber. It is clear, therefore, that by far the larger proportion of the acid has thus been made in the upper portion of the chamber, while the figures in Table X. would indicate that all the sulphuric acid must have been produced within the space between the roof of the chamber and the top tray, or, say, one-fourth the total height of the chamber.

We are safe, therefore, in drawing the general conclusion that almost all the acid is produced in the higher portion of the chamber. That this is quite in accordance with what might be looked for, we have only to examine the relative specific gravity of the gases at 0° C., compared with air—

SO <sub>2</sub> .....	2.217
SO <sub>3</sub> .....	2.760
N <sub>2</sub> O <sub>2</sub> .....	1.039
Air .....	1.000
H <sub>2</sub> SO <sub>4</sub> .....	1.430.000
Water .....	773.000
NO .....	1.589
Steam (100 C).....	.47

and to consider that we have to deal with matter in two forms, gaseous and liquid, the latter being in the form of a mist or spray of sulphuric acid, which being so very much heavier than the gases with which it is mingled, rapidly falls towards the bottom of the chamber, displacing the gases and forcing them to the upper portion, where naturally their condensation must take place. The average specific gravity of the gaseous matter may be roughly taken as about 2.00, while the sulphuric acid H<sub>2</sub>SO<sub>4</sub> has a specific gravity of 1.430.00, more than sufficient to account for the relative positions in the chamber. The figures which I have obtained, no doubt, show certain irregularities in the yield obtained at the various points of the chamber, but this is, I think, accounted for sufficiently by the agitation and whirl of the gases, induced by the strong effect of the steam jets entering the chamber and the constant current flowing in and out of the chamber. To what practical conclusion, then, do these results lead us? I think simply to that of having ample chamber space, the form of the chamber not being so material. With low chambers the power of mixing the gases is deficient, and a scarcity of nitrous compounds at any time does more harm from the going through of the chambers, while in high chambers there is more chance of the gases being thoroughly intermingled, and this "going through" is much more rare. What form of chamber will give the best results is a difficult question to answer, as the question of space is complicated with the question of "surface condensation," which plays a very important part in the production of the acid. That this is so is easily seen by watching, through the open door of a chamber, the constant drop of acid formed upon the roof of the chamber. The use of increased condensed surface has been often proposed, and notably by Mr. Ward, who proposed using piles of glass sheets, separated from each other by about an inch of space, and placed in chambers. The effect of surface upon the production of sulphuric acid was also investigated, and a tray, as nearly as possible one square foot area, suspended in the chamber, was found to give a quantity of 708.75 grms. H<sub>2</sub>SO<sub>4</sub>. Placing now in the tray, in a vertical position 1 in. apart, 12 pieces of glass, each 12 in. by 6 in., the amount of acid obtained in 24 hours

was 1644grms.  $H_2SO_4$ . This would show the condensation due to the glass is  $= 1644 \div 708.75 = 935.25$ grms., and as the surface exposed was equal to 12 square feet, the acid condensed on the glass surface was equal to 79grms. per square foot, the glass being vertical. Placing now the glass horizontally and carefully at the same distance apart as before, the acid obtained in 24 hours amounted to 3,226grms.  $H_2SO_4$ , giving  $3226 \div 708.75 = 2517.25$ , this being equal to 209grms. per square foot. If we take the amount produced in the tray without glass as being equal to 100, the relative proportions will be—

Tray without glass .....	100
Tray with glass, vertical .....	231
Tray with glass, horizontal .....	455

This enormous increase in the condensation ( $4\frac{1}{2}$  times) indicates how important a factor surface available for

shield or cover over it, to prevent any acid from the upper portion of the chamber falling upon it, and these condensers were arranged at three heights, 5ft. 3in., 10ft., and 14ft. 6in. from the bottom of the chamber. The acid obtained by condensation upon this surface was measured at fixed hours, and the results tabulated daily. The observations were carried on for several months, and the average amounts obtained were—

DRAWING A. Arrangement of Lead Surfaces.

condensation is in deciding upon the most advantageous form of chamber; but there has also to be considered in connection with the question the cost of erection. The chambers in the form of a cube would have the advantage of giving the maximum space with the minimum of lead; but in so far as surface condensation is concerned, it is clear that this would be the worst form of chamber that we could adopt. Some further experiments were made with a series of drips and trays, arranged as in the drawing marked A. These, which might be called surface condensers, were arranged in pairs, and means for collecting and measuring the acid condensed upon them were provided. One of each pair had a

confirming very completely our previous results, and further proving that the chief condensation took place in the upper portion of the chamber. In drawing B the arrangement of these "surface condensers" is shown in the first division. Six trays were arranged as in drawing A, each 1 foot square, and also a series of flat trays with surfaces of 1, 2, and 4 square feet respectively. These were used in order to find, if possible, the amount of condensation practically in proportion to the surface exposed, the figures being—on the 1 square foot, 100; on the 2 square feet, 199.2; on the 4 square feet, 403.

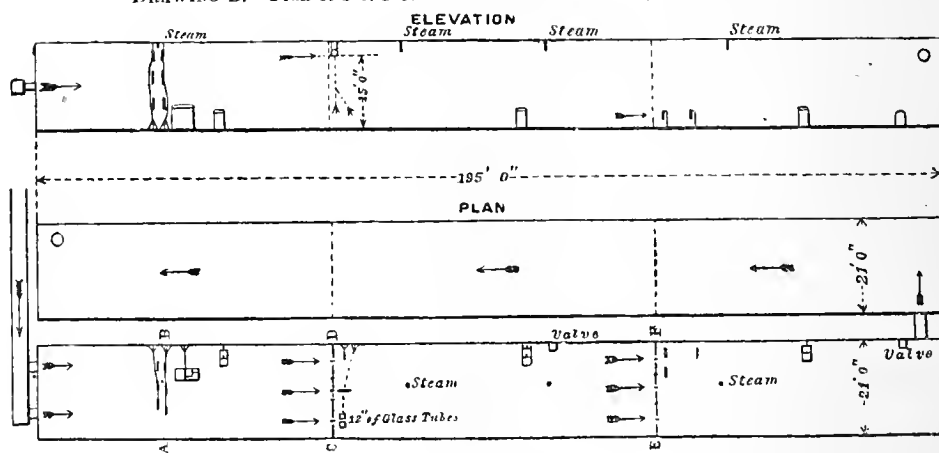

In the second division of the chamber the arrangements of the "surface condensers" were such that one

of them faced the current entering the chamber, and had its run-off pipes so arranged that the amount of acid formed on each side could be measured separately. The proportion obtained on the flat surface facing the current being taken as 100, the amount formed on the "lee" side, away from the current, was 78. Another "surface condenser" was placed with its edge towards the gas inlet, and the amount obtained from the double surface was 175, as compared with 178, in the previous cases. There being three openings in the curtains, opposite the third one was placed a pair of leaden trays of 1 square foot area. One of these had, in addition, slips of glass, 1 square foot area, placed in it vertically, and the amounts of acid obtained were in the proportion of 100 from the simple tray, and 192 from the tray with the extra 1 square foot of glass surface. These results show how very important, indeed, the question of surface is in connection with condensation, but the question of the best form of chamber is so involved with the question of cost, tear and wear from lead surface exposed, etc., that it would require a very large amount of calculation and experience before one could decide what form of chamber was the cheapest to erect, keep in repair, and give the best results as to

teicular leads, which are so pure and do not stand the action of sulphuric acid in the cold, are also the least suitable for chamber purposes, and whether the ordinary test which is applied for such lead—that is, merely ascertaining the amount of hydrogen evolved in a given time from a given surface—is also a sufficient test of lead for chamber purposes. That test has been objected to, on the ground that the conditions which exist in chambers are different. It would be very interesting to know whether the different portions of the chamber—that is, the lead at the different zones or regions of it—is acted upon differently according to the nature and composition of the gases at these particular points, and generally, whether the lead which behaves worst under sulphuric acid alone, is also most acted upon under chamber conditions.

Mr. BOYD (St. Rollox): As for the tests we use for "chemical lead," we have none of any great value. The hydrogen test was used for a considerable time, but we gave it up, as the results were misleading. Chamber lead is not so liable to be destroyed by the action of sulphuric acid as by the nitrous compounds. The action is different, and varies much with the position of the lead in the chamber. For

DRAWING B. Plan of No. 2 Series of Chambers.—Scale, 40 feet to one inch.

condensation and acid. I place these remarks before you merely as a contribution towards the solution of the problem, and I trust that the subject will be taken up by others and worked out still more fully.

#### DISCUSSION.

Mr. R. R. TATLOCK: I would like to ask as to the behaviour of the lead in the different zones or regions of the chamber. We have heard a great deal in our day about "pure chemical lead," but most of us know that this is now considered a contradiction in terms, and that pure lead is far from being well suited for many purposes connected with vitriol, particularly for the manufacture of the lead boxes in which vitriol is packed for export. Sometimes these are bulged to such an extent that the cube becomes almost a complete sphere on account of the action of the lead on the sulphuric acid and evolution of hydrogen. Sometimes in the lead pans also there is strong action, which seems to be due to the purity of the lead, because that lead, on analysis, shows usually mere traces of impurities. I should like very much to know if Mr. Boyd can tell us whether the par-

chambers and for concentrating pans we try to get as pure "virgin" lead as possible, containing its full amount of silver derived from the ore, and that has never been treated by any of the processes for desilverisation. But even the most carefully-selected sheets go wrong in the concentrating pans, and there is sometimes no accounting for it. A good deal depends on the workmen having temperature, strength, and supply of acid in good order.

Mr. STANFORD: I would simply rise to propose a vote of thanks to Mr. Mactear for the excellent paper he has given. It involves a considerable amount of labour, and gives us some indication of an attempt to solve that very important problem, "how to make the best vitriol chamber." It does seem a little remarkable, after all we know already, and all that Mr. Mactear has added to our knowledge of vitriol condensation and the great value of surface condensation, that we should still be obliged to use such large spaces to condense vitriol. The time is, I hope, coming when some smaller arrangements may answer the purpose. At present, I think Mr. Mactear has himself admitted that we have not yet arrived at even the proper shape of the vitriol chamber.

# Journal and Patent Literature.

## II.—FUEL, GAS, AND LIGHT.

*The Scheurer-Kestner Experiments on the Employment of Coal in Steam Boilers.* Ferd. Fischer. Dingl. Polyt. Jour. 251, 323.

SCHAUER-KESTNER used a narrow platinum tube (*vide Bulletin de Mulhouse* 1868, pp. 211 and 215) for taking the samples of gas, the slit of it being only a few tenths of a millimetre wide. A stream of gas was continuously aspirated through the tube for several hours by means of a water pump, 0.4 to 0.2 per cent. of the gas being sucked into a flask, by allowing mercury to flow out, for subsequent analysis. The difference in pressure between the mercury flask and the external air was 2mm. to 3mm. of mercury, but it rose as soon as the slit began to choke. As the action of the water air-pump could not be quite uniform, and the draught in the chimney was not steady, and the composition of the gases of combustion greatly varied (*Bulletin*, 1868, p. 337, and 1869, p. 250), it cannot be considered that a really average sample was obtained. The examination of the gases taken in this manner gave the following results:—

No. of the Experiment.	Carbonic Acid.	Carbonic Oxide.	Carbon Vapour.	Hydrogen.	Oxygen.	Nitrogen.	Excess of Air.	Highest Temperature of the Smoke Gases.	Coal burned on 1 sq. m. grate surface per hour.	Duration of Aspiration.
1	13.08	0.83	—	—	4.84	81.25	pr. ct.	—	K	Hrs
2	7.73	0.11	—	—	11.42	80.44	—	—	45	35

4	13.80	—	0.86	1.06	5.53	78.75	—	—	—	1
5	8.62	—	0.14	0.53	10.83	79.88	—	—	45	8
6	13.21	—	0.32	1.08	5.27	79.92	—	—	—	8
7	8.23	—	0.04	0.52	11.35	79.86	—	94°	16.6	3
8	12.89	—	0.23	0.96	5.53	80.34	—	93°	23	3
9	14.63	0.86	0.49	0.56	2.80	80.66	—	132°	47	3
10	10.87	—	0.19	0.19	8.99	79.76	—	156°	92.5	3
11	14.16	0.97	0.98	1.11	2.18	80.60	—	128°	47	—
12	14.87	0.84	1.15	1.35	1.41	80.38	—	66°	119	40
13	13.34	—	0.46	0.91	3.77	81.52	—	176°	135	40
14	13.13	0.24	0.32	1.41	4.42	80.18	—	20.91	—	40

The coal employed in these experiments had in round numbers the following composition:—

Carbon	70.0
Hydrogen	4.0
Oxygen	4.0
Nitrogen	1.0
Ash	21.0

100.0

Scheurer-Kestner concludes (*Bulletin*, 1868, p. 319) that the products of combustion contain the smallest quantity of combustible gases, when 10 cubic metres of air are supplied for 1 kilo. of coal, *i.e.*, about double the quantity theoretically necessary. This conclusion has given rise to the erroneous idea that twice the theoretical quantity of air must always be supplied, whereas F. Fischer has shown (*Dingl. Polyt. Jour.* 232, 345, and 250, 75) that it is better to admit less air. For estimating the loss in the smoke, samples were taken in the way suggested by Sainte Claire-Deville. A horizontal pipe was introduced into the heating flue, provided with openings on the top side, so that when water was made to flow through, the gases were sucked along with it and collected in a gasometer. Five samples taken in this manner had the following composition:—

I.	II.	III.	IV.	V.
Nitrogen.....	87.18	87.60	86.60	85.78
Carbonic acid ....	7.16	5.27	3.33	5.63
Oxygen .....	4.66	7.16	9.86	8.58

On the strength of the foregoing fourteen analyses and of six other analyses of smoke gases, Scheurer-Kestner assumes that the combustion gases contain 1 per cent. combustible gas, so that with 21 per cent. oxygen in the

air the actual composition of the gases may be accepted as under (*Bulletin*, 1868, p. 328, and 1869, p. 273):—

	I.	II.	III.	IV.	V.
Nitrogen.....	79.0	79.0	70.0	79.0	79.0
Combustible gases	1.0	1.0	1.0	1.0	1.0
Oxygen .....	4.1	7.3	9.6	7.8	11.2
Carbonic acid.....	15.9	12.7	10.4	12.2	8.8

On the basis of this bold assumption further calculations are made. The following experiment with Friedrichsthal coal may serve as an example (*Bulletin*, 1869, pp. 295 and 347):—

April.	Coal burned.	Water evaporated.	Amount of Oxygen in Gases.			Temperature.		
			Highest.	Lowest.	Mean.	Of the Water.	Of the Smoke.	Of the Air.
17	1063	6870	11.1	5.8	10.0	10.0	121	18
18	963	6000	9.1	6.1	8.0	9.8	108	20
21	1010	6250	10.2	5	8.1	10.0	113	19
24	918	6050	13	6.3	8.7	11.0	98	22
25	955	6500	13.5	9.3	10.7	11.0	111	24
			mean	9.1	10.5	110	20.6	

From this it follows—

	Per cent.
Amount of oxygen found .....	9.1
Correction .....	2.3
Amount of oxygen.....	6.8

From this it is further concluded that the combustion gases contain 12.2 per cent. carbonic acid, and that for 1 kilo. coal, 10.715 cubic metres nitrogen and air, along with 1.485 cubic metre carbonic acid escaped. These correspond to a water value of 3.705 kilos., or at 101.4 excess temperature to 372 cal. It is further assumed from the 20 analyses that 5.5 per cent. carbon and 15 per cent. hydrogen escaped unconsumed, corresponding to 595 cal., that 1 per cent. carbon escaped in the smoke, corresponding to 63 cal., and that 282 cal. were carried away by the water vapour in the smoke gases, thus—

	Cal.
Steam .....	5013
Gases .....	372
Combustible gases .....	595
Soot .....	63
Water vapour.....	282
	6325

The calorimetric estimation of the average sample gave 8,457 cal., so that 2,132 cal., or 25.2 per cent., were lost by conduction and radiation. "The calculations of loss thus rest simply on the oxygen determinations in samples taken over water, and on assumptions and inferences of so bold a nature that serious criticism is disarmed." The writer considers it his duty to draw attention to the great defects in these boiler experiments, and to warn against the false conclusions which have been drawn from them.—W. M.

*Researches on the Use of Combustibles for Heating Steam Boilers.* Scheurer-Kestner. Bull. de la Soc. de Mulhouse, Nov.-Dec., 1883.

THIS is a reply to the different criticisms that have appeared on the results of some experiments undertaken by the author in conjunction with M. Meunier Dollfus, and published some fifteen years back. The plan followed was to determine the heat of combustion of the substance under examination in a Favre-Silbermann calorimeter, comparing the result with the value obtained for wood charcoal in the same apparatus. After this the substance was tried against wood charcoal under a steam boiler. The reply refers chiefly to the statements of M. Bunte, who has been commissioned by the Society of Munich to investigate the properties of the principal fuels

of South Germany. The author contends that the apparatus in which M. Bunte professed to determine the heat of combustion and the quantity of heat which may actually be utilised in practice by one and the same experiment was an imperfect calorimeter, and this assertion he supports by showing that M. Bunte has lost in the case of coke from 1.3 per cent. to 4.7 per cent. of the true calorific power. Moreover, he has never proved the accuracy of his apparatus by burning a substance such as wood charcoal, of which the heat of combustion is perfectly established—a precaution always adopted by M. Scheurer-Kestner. This is the more extraordinary, as M. Bunte himself discovered, after 29 experiments, that his results were, on his own showing, 14 per cent. too low, from heat lost by radiation, and he had to make some alterations in his apparatus to insure a more perfect conservation of the heat. One of the principal facts brought to light by M. Scheurer-Kestner, and most strongly attacked by M. Bunte, was that certain coals give a greater heat of combustion than is afforded by the addition of the heats of combustion of their hydrogen and carbon. The author shows, however, that M. Bunte has actually corroborated this in some of his researches, but in all cases he has drawn false conclusions from his results, by not taking into consideration the ash of the combustible. When this defect is remedied in the calculations his results are seen to be, on the whole, far too low to allow implicit confidence to be placed in them. M. Bunte appeals for support to the experiments made by M. Stohmann, of Munich, with a new apparatus (which is, in fact, only a modification of Frankland's calorimeter, given up by the inventor as inaccurate). As, however, this does not allow an estimation of the ash of the combustible used, and as no account has been taken of this ash, the results cannot be allowed to weigh with those obtained from a calorimeter of such known excellence as the Favre-Silbermann. In his experiments on the amount of heat which may actually be utilised in practice, the author came to the conclusion that about 25 per cent. is lost, and cannot be traced by known methods of investigation. M. Bunte thinks these figures far too high, but M. Scheurer-Kestner points out that a similar result was obtained when pure wood charcoal was used. M. Weinhold, referring to the analyses of the gas produced by combustion, prefers to collect the sample over water covered with oil, but the author thinks his own plan of using mercury is better. M. Fischer is somewhat hypercritical, complaining that the specific heat of a mixture of oxygen and nitrogen in the gases from the combustion is reckoned as the same as common air; the correction would make a difference of only six calories in 7218. His other remarks show a complete ignorance of the method in which the author's researches have been conducted.—A. R. D.

*Russian and Roumanian Petroleum.* Seifensied. Zeit.  
33, 395.

THE mercantile report of Tilsit contains the statement that the importation of American petroleum to Russia has wholly ceased. Russian petroleum is cheaper than American, and it is probable that in a few years Russia will not only produce sufficient for her own supply but will even export. Roumanian petroleum will probably become of importance for the supply of Eastern Europe, it being reported that an immense petroleum basin has been discovered. In Breslau, Russian petroleum of good quality from Baku is placed in the market 8 per cent. below the price of the American oil.—A. H. A.

*Testing Petroleum for Adulteration with Solar Oil.* Dr.  
G. Heppel. Chemisch.-techn. Central-Anzeiger.

COMMERCIAL petroleum is said to have a density of from 0.795 to 0.804, solar oil from 0.830 to 0.870, so that a density of the sample higher than 0.804 points to the presence of solar oil. The boiling point of ordinary petroleum is said to range from 180° to 250° C., and that of solar oil between 240° and 300° C. In treating petroleum with concentrated sulphuric acid the oil remains colourless, and only the acid is coloured a light brown. If solar oil be thus treated, the sample becomes brown, and the acid a dark reddish-brown. On treating

a mixture of the two bodies with acid, the colour of the oil is the more intense in proportion to the quantity of solar oil present. After some hours, the red-brown colour of the oil changes to violet-red, whilst the acid remains brown. The foregoing method is not very satisfactory should it happen that the petroleum has been badly purified on the one hand and good solar oil has been used on the other. The author has devised a method which gives good results with American petroleum, but he has not yet examined other oils with it. The sample is treated with perfectly dry copper butyrate in powder. The salt will dissolve, giving a bluish-green colour to the solution, which is now heated. If solar oil be present a yellow colour is produced at 120° C., with separation of yellow flocks, the quantity being in proportion to the amount of the admixture. If this oil be absent, the oil remains green and clear, even at a temperature of 210° C. Upon cooling the solution, a yellowish-brown precipitate is at first thrown down, and upon this a second precipitate of a greenish-blue colour, the liquid above being a pale yellow. The first precipitate is due to the solar oil, the second to the petroleum. When the sample is unadulterated, the liquid above the precipitate due to petroleum, is almost colourless. The copper butyrate employed was prepared from ordinary commercial butyric acid.—A. H. A.

*Improvements in the Manufacture of Gas and Apparatus Employed Therein.* Sydney Pitt, Sutton. Eng. Pat. 2544, May 22, 1883.

By means of any kind of heating gas conducted into a chamber partly filled with lime, and burned with air under pressure, this lime is raised to an intense heat. Steam (preferably superheated) and naphtha, or some other liquid hydrocarbon, are then introduced. The resulting gaseous mixture, consisting mainly of hydrogen and carbonic acid, is passed through a cooler into a governing holder, which maintains a constant pressure upon the gas. The carbonic acid is next removed by a passage through chambers partly filled with cold quicklime, care being taken to have a certain quantity of moisture present. Almost pure hydrogen is now left, which may either be used as such or else first carburetted by being passed through a chamber filled with brick or other refractory material raised to a high temperature in the way described above, and into the top of which naphtha or its equivalent is introduced. This is converted into a fixed gas by the hot material, and mixing with the hydrogen passes away to the distributing holder. When the quicklime used for absorbing the carbonic acid has become spent, it may be regenerated by being heated in the same way as the lime and brick chambers above. By another portion of the invention an independent generator for the heating gas may be dispensed with by burning the hydrocarbon with air in the first lime chamber until the temperature is sufficiently raised, and then stopping the air supply and admitting steam. When the temperature falls again below the point of conversion air is again admitted, and a fresh combustion of the hydrocarbon reheats the apparatus.—A. R. D.

*Improvements in Gas Generating Furnaces.* L. Mond, Northwich. Eng. Pat. 3821, 1883.

THE inventor claims (1) the manufacture and use of gas generating furnaces having air-admission grates in the form of a long slit or slits, or grate or grates, or number of orifices near together, so as to accomplish the same result, extending nearly or quite the entire length of one, or preferably two, opposite sides of the producer chamber, and at a distance above the opening through which the ashes or clinkers are withdrawn, and (2) the manufacture and use of rectangular gas-generating furnaces, having two working fronts opposite each other, through each of which air, or air and steam, or air and other gases, can be admitted, and which allow the furnace to be clinkered from both sides. The advantage of this producer is that every part is very accessible when working. The air is admitted from the outside into grates almost incapable of being impeded by clinker,

the fuel can be got at by working bars from every side, and the clinker can be cleaned out without in the smallest degree disturbing the working of the producer from either or both sides of its chamber. Thus, inferior kinds of fuel can be used, such as slack, shale, and other dirty fuel not fit for other gas producers.—D. B.

*Apparatus for the Manufacture and Treatment of Gas.*  
J. E. Dowson, London. Eng. Pat. 3406, July 10, 1883.

THE inventor surrounds a fire for generating heating gas with a double casing containing water. This double casing communicates at the bottom by means of pipes with a coil in which steam is produced, and superheated by a fire suitably applied. Part of the steam is conducted to the top of the space within the double casing, so that water is always forced into the coil under pressure, and part is conducted to an injector, whence it passes with air into the generating fire. Within the gasholder are two scrubbers, and the gas from the generator is conducted up through one into the holder, and has to pass down through the other to where wanted.—A. R. D.

*An Improved Regenerative Gaslighting Apparatus.*  
Anthony Spencer Bower, St. Neots, and Thomas Thorp, Whitefield, Lancaster. Eng. Pat. 3742, July 31, 1883.

THE gas is burnt from a ring burner, composed wholly or in part of steatite, having the necessary perforations in its periphery. The heated products of combustion are deflected towards the centre by a perforated annular curved plate, and pass upwards through a series of vertical tubes in a closed chamber (forming the "primary regenerator") to the chimney. The air necessary to combustion is introduced through and heated by the "secondary regenerator," which is formed by a number of plates attached alternately to the bottom plate of the primary regenerator, and to the upper side of the curved deflector; thence it passes, partly through the perforations of the deflector into the glass containing-globe, but mainly into the primary regenerator; and thence through one tube surrounding the gas supply pipe to the interior of the flame, and through a second, passing within the gas pipe, to the exterior of the flame. "The secondary regenerator heats that portion of air admitted directly to the globe, and also partially heats the whole of the air supplied through the primary regenerator for combustion with the gas." A slight modification of the arrangement is made for use with table lamps.—W. G. M.

*Improvements in the Manufacture and Purification of Illuminating and other Gases, and in Apparatus used in such Manufacture and Purification.* Alexander Gibb Henderson, Wood Green, and James Anderson Kelman, High Holborn. Eng. Pat. 3708, July 30, 1883.

THIS invention relates first to a new form of washer scrubber. It consists of an upright case divided horizontally into eight compartments. The floor of each chamber is kept covered with water to a certain depth by means of overflow pipes, the water being constantly renewed from above, and the saturated water drawn off from the lowest chamber. The gas enters through the lowest division, thence passes upwards through bell-mouthed tubes, supplied with distributing caps, of which several are fitted through the floor of each chamber, and thus to an outlet in the uppermost compartment. These distributing caps serve to slightly water-seal the tubes, and are fitted interiorly with curved vertical divisions, which cause the gas to divide and give it a circular motion, inducing whirlpool currents in the water. Secondly, "to the condensation and partial purification of the gas preparatory to its passage to the water-scrubber." This is effected in three vertical multitubular vessels arranged side by side. Each vessel is provided with an open water chamber above and a closed one below, and with one or more perforated discs dividing it into horizontal compartments. The perforations are somewhat larger than is required for the vertical tubes to pass through, the area of the excess being at least equal to that of the gas supply pipe. The gas enters at the top of one of the chambers, is cooled by the water and the discs, leaves at the

bottom, and is passed to the top of the second chamber, finally leaving at the bottom of the third vessel. The water flows in a contrary direction; cold water is supplied to the closed chamber beneath that vessel, through which the gas passes last, rises through the tubes to the upper cistern, thence to the lower cistern of the vessel next in order, and so on, the circulation being maintained by the heating of the water. Thirdly, to the recovery from the liquid deposited in the hydraulic main of certain illuminating properties of which the gas has been deprived while passing through the main, and of restoring the same to the gas before passing through the condensers, and also to the partial purification of the gas so treated. The liquid from the hydraulic main is caused to trickle over perforated serpentine plates, through which the gas is passed several times, in a large upright chamber, thence the liquid flows over steam pipes in a lower compartment, giving up volatile hydrocarbons to the enrichment of the gas, and is finally removed by a trapped outlet pipe beneath. The gas passes in a contrary direction to the fluid.—W. G. M.

*Treating Spent Lime from Gasworks.* W. R. Lake, London. Eng. Pat. 3657, July 25, 1883.

THE spent lime is thoroughly leached with hot water or steam, and the resulting liquor treated in a closed vessel with a stream of carbonic acid gas. Sulphuretted hydrogen is disengaged and conducted away to a chamber, either to be absorbed by hydrated oxide of iron or to be burned for the manufacture of sulphuric acid. Sulphocyanide of lime is left in the closed vessel, and this is decomposed by the addition of sulphate of potash. The liquor is separated from the precipitated sulphate of lime, and the salt yielded by its evaporation is used in the manufacture of ferrocyanides.—A. R. D.

*Improvements in the Manufacture of Hydrogen Gas.*  
Sydney Pitt, Sutton. Communicated by Erazm. J. Jerzmanowski, New York, U.S.A. Eng. Pat. 5709, Dec. 11, 1883.

A MIXTURE of hydrocarbon vapour and steam is passed successively through two chambers containing respectively lime and anthracite (previously heated by the combustion of hydrocarbon vapour within them). The carbonic acid, which, together with hydrogen, is the product from the first chamber, is thus converted by the red-hot anthracite into carbonic oxide; the resulting mixture of hydrogen and carbonic oxide, after washing, is ready for use. Or the water gas may be prepared in another way. Two or more cupolas filled with anthracite, and provided with a pair of air regenerators, are connected with an ordinary gas producer. The gases from the latter are employed to heat the anthracite in the first cupola, and afterwards one of the regenerators; they are then diverted to the second pair, the air used for the combustion of the gas in the second cupola being heated in the first regenerator. Meanwhile a current of steam is passed through the first cupola, thereby yielding the required gas until the temperature of the anthracite has fallen too low, when the producer gas is again passed through this cupola, and the steam is allowed to act upon the now heated anthracite in the second generator. Thus a constant stream of water gas is obtained, which may be washed and stored for use.—W. G. M.

*The Purification of Coal Gas.* Miles Williams, Wigan. Eng. Pat. 3642, July 4, 1883.

IN order to save the nuisance of removing the oxide of iron from the purifiers, and of exposing it to the air for revivification, atmospheric air is drawn into the main (before the gas reaches the purifiers) in such proportions as to revivify the oxide. This air is first charged with the vapours of petroleum or some other hydrocarbon—but not gas tar—so that the illuminating power of the gas is not decreased. By this means the oxide can be left in the purifiers until it is so charged with sulphur as to be of no further use for the purpose.—A. R. D.

*Apparatus for Carburetting Gas and Air for Lighting and Heating Purposes.* John Thomas, London. Eng. Pat. 3359, July 6, 1883.

A RESERVOIR containing the hydrocarbon to be used for carburetting is connected by a pipe with a smaller vessel containing asbestos cloth, some of which passes down the connecting pipe and dips into the hydrocarbon, so that this latter passes into the smaller vessel by capillary attraction. The mixture of gas and air is first heated at the burner, and then passed through the smaller vessel. For heating, a larger proportion of air is required than for lighting purposes.—A. R. D.

### III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

*On Acridine Picrate.* R. Anschütz. Berl. Ber. 17, 438.

IN an investigation of the hydrocarbons present in crude phenanthrene the author treated the substance with an alcoholic solution of picric acid, and obtained a small quantity of a picrate, which was very slightly soluble even in boiling alcohol. An examination and analysis of the substance showed that it was acridine picrate

By rapid crystallisation from alcohol acridine picrate forms microscopic prismatic needles; by slow crystallisation it forms hard prisms grouped in stars. The salt possesses a canary yellow colour and melts above 208°, at which temperature it begins to blacken. It dissolves with great difficulty in cold water and is partially decomposed by boiling water, the smell of acridine being easily recognised. Acridine picrate is also very slightly soluble in cold alcohol and benzene, and the solubility is not much increased by boiling. Acridine may therefore be frequently employed in the analysis of picrates, the hydrochloride, for instance, in the analysis of picrates, and the free base in that of the picric acid compounds of hydrocarbons. In order to avoid the difficulty of washing the precipitate thoroughly with benzene when on a paper filter, the author recommends the employment of a platinum crucible the bottom of which is perforated and covered with asbestos. Many of the acridine bases appear to form difficultly soluble picrates. Thus the chrysianiline compound is a brick-red powder which is almost insoluble in benzene. It is possible that a more insoluble picrate than that of acridine may be found, but this substance appears to give as good results as ammonia in the analysis of picric acid.—S. Y.

*II. On High-boiling Phenols contained in Coal-Tar.* Communications by E. Noelting. Berl. Ber. 17, 385.

IT is well known that phenols are contained in the high-boiling portions of coal tar, but their nature has not been studied. Some years ago the author obtained colouring matters by combining the phenols with diazo compounds. Thus sulphanilic acid gave a yellow-brown, and naphthionic acid a red-brown colouring matter, which, however, were not to be compared with those prepared from naphthol, etc. In order to study the nature of the phenols, the raw product, obtained by treating the tar oils with caustic soda and precipitating with an acid, was fractionated *in vacuo*, and the portion above 300° investigated. The crude products were obtained from Messrs. Vale and Company, in Hamburg, and Messrs. Dittler and Company in Höchst. The removal of the hydrocarbons still present in the distillate was effected by neutralising with caustic soda, diluting with a large quantity of water to precipitate smeary impurities, and extracting the hydrocarbons by agitation with toluene. The phenols were precipitated with an acid, extracted with ether, and distilled with zinc dust, and the semi-fluid mixture of hydrocarbons was at once oxidised with chromic acid. Small quantities of phenanthrene quinone and anthraquinone were found among the oxidation products. Hence it is probable that the phenols of phenanthrene and anthracene are present in the tar oil, but it is certain that a great number of other phenols are also contained in it.—S. Y.

*On Acridine.* L. Medicus. Ber. 17, 196.

THE recent adjustment of the formula for acridine induced the author to resume his former investigations on a nitroso-compound of acridine. On treating a solution of a salt of acridine with a solution of an alkaline nitrite, a light yellow flocculent precipitate is produced, which, when crystallised from hot water, forms long, yellow, silky needles, melting at 150°–151°. The compound is sparingly soluble in cold water and ether, dissolves in hot water, and is readily soluble in alcohol. Its solutions exhibit the fluorescence which characterises the salts of acridine. Analysis gave numbers corresponding to the formula

The author found that by the action of zinc and hydrochloric acid on this compound acridine is reproduced. D. B.

*Hydrocarbons and Alcohols obtained from American Petroleum.* G. Lemoine. Ber. 17, 132, and Bull. Soc. Chim. 41, 161.

THE hydrocarbons, octyl-, nonyl- and decyl-hydrides obtained from petroleum by fractional distillation were separated from the unsaturated hydrocarbons by treatment with bromine. Octyl-hydride has a specific gravity of 0.732 at 12.1°, and boils at 121° at a pressure of 779mm., at 82° at 2120mm., at 63° at 100mm., and at 31° at 27mm. Nonyl-hydride: (1) Boiling point 135–137°; specific gravity 0.742 at 12.4°. (2) Boiling point 129.5–131.5° at 751mm., 59–60° at 65mm., 37.2–40° at 22mm.; specific gravity 0.743 at 0°, 0.734 at 12.7°, 0.731 at 16°, and 0.725 at 24.7°. Nonyl-chloride was prepared from a nonyl-hydride boiling at 132° at a pressure of 759mm. It had a specific gravity of 0.911 at 23°, 0.908 at 25.8°; boiling point 180–184°. Nonyl-alcohol obtained from nonyl-hydride, boiling at 130–135°, had a specific gravity of 0.855 at 18.5°, and boiled at 133–136°. Decyl-hydride: Specific gravity 0.764 at 0°, 0.753 at 15.6°, 0.751 at 17°, 0.739 at 33.5°; boiling point 151–160° at 757mm., 67.5° at 36mm. Decyl-chloride: Specific gravity 0.908 at 190°; boiling point 201–203°. Decylene: Specific gravity 0.855 at 14°; boiling point 159–174°. Decyl-alcohol: Specific gravity 0.858 at 18.5°; boiling point 200°.—D. B.

*Note on (1) the Behaviour of the Nitrogen of Coal during Destructive Distillation, and (2) a Comparison of the Amounts of Nitrogen left in Cokes of Various Origin.* By Watson Smith. Journ. Chem. Soc. April, 1884.

MR. WM. FOSTER, at the close of his interesting paper read before the Chemical Society, and published in its Journal (1833, Trans. 105–110), summarises his results as follows:—

Percentage of nitrogen in the coal .....	1.730
Percentage of nitrogen of coal evolved as ammonia during destructive distillation ..	0.251
Percentage of nitrogen in coal evolved as cyanogen during destructive distillation ..	0.027
Amount of nitrogen remaining in coke furnished by 100 parts of coal .....	0.842
	1.120
Nitrogen from 100 parts of coal unaccounted for, the larger portion of which is presumably present as free nitrogen in the coal-gas. Some is no doubt in the tar .....	0.610

If we further reduce these figures to percentages on 100 parts of nitrogen, their relation to each other becomes more intelligible:—

Nitrogen of coal evolved as ammonia .....	14.50
Nitrogen of coal evolved as cyanogen .....	1.56
Nitrogen of coal present in the coal gas in the elementary condition .....	35.26
Nitrogen of coal remaining behind in the coke .....	48.68
	100.00

“I have not made any experiments on the amount of nitrogen in the tar, nor am I in possession of any information on the subject, but I have assumed that the quantity is relatively small.” Mr. Foster’s last remark referring to the amount of nitrogen in the tar interested the author on first reading it, and for the following reason: As far back as the year 1868, when making distillations either

of coal tar or crude coal-tar oils, he observed, whenever the distillations were carried so far that pitch remained in the retort, and these residues of pitch were further heated until partial coking took place, that on leaving the whole to cool partially, and then removing the stopper of the retort, a smell of ammonia was always perceptible, reddened litmus paper was turned blue, and a stopper moistened with hydrochloric acid fumed strongly. Certain tar distillers aver that after coking pitch, when the manhole lids of the stills have been removed, the odour of ammonia is very powerful. The experiment is so easily performed with a little hard pitch broken up small and placed in a retort and heated to coking, that it would form a very good lecture experiment, to illustrate the fact that nitrogen compounds of considerable stability exist in hard pitch and in partially-coked pitch, and that at temperatures near the softening point of glass these compounds are so decomposed that on partial cooling and in contact with moist air ammonia is evolved. It is a remarkable fact that not the slightest smell of ammonia could be perceived, if the retort-stopper were removed whilst the retort is still very hot. The most favourable time for obtaining the evidence of the presence of ammonia is when the retort has cooled so far that its bulb may be held in the hand. The author supposes that the nitrogen in the partially-coked pitch has been brought into so unstable a form of combination, that, on cooling down and a back-suction of moist air into the retort taking place, such unstable nitrogen compounds in the highly-porous mass in presence of moisture are decomposed or altered so as to yield ammonia. It was determined to attempt to estimate the amount of nitrogen in ordinary coal tar and in the oils obtained at different stages from that tar, as well as in the pitch left as a residue. The numbers given are the means of at least two experiments for each sample. The tar analysed was thoroughly well settled from ammoniacal water, but beyond this no attempt was made to remove suspended solution of ammoniacal salts. The crude benzene contained ammonia in solution, which communicated to it a pungent odour. The "light oil" likewise smelt slightly of ammonia, but the "creosote oil" was quite free from ammoniacal odour. *Nitrogen in the Tar:* The mean of two experiments gave 1.667 per cent.

Crude benzene, obtained from the above tar (mean of two experiments) .....	= 2.327
"Light oil," obtained from the above tar (mean of two experiments) .....	= 2.186
"Creosote oil," obtained from the above tar (mean of two experiments) .....	= 2.005
Red oil, or oils from which the crude anthracene had been separated by filtration (mean of two experiments) .....	= 2.194
Pitch, obtained from the above tar (mean of two experiments) .....	= 1.595

It would thus appear that nitrogen compounds of high boiling points occur in the oils drained from the crude anthracene to a considerable extent, and that though there is a falling off in the pitch (in the above case a hard pitch), yet still in this product certain very stable nitrogen compounds occur; further, that the amount of nitrogen contained in ordinary coal-tar oils (from Lancashire coal tars) may be stated as 2 per cent. on the average. Of course the lighter naphthas will contain the pyridine bases, the intermediate naphthas and oils, more especially the quinoline bases, whilst the anthracene oils and pitch will contain the carbazols and acridine, and possibly other nitrogenous bodies of high boiling and melting points not yet examined. *Comparison of the Amounts of Nitrogen left in Cokes of Various Origin:* Three varieties of coke were now analysed, with the object of determining the nitrogen in them, viz., ordinary gas-retort coke, Beehive metallurgical coke, the hard compact metallurgical coke from the Simon-Carvès coke-ovens. The results are as follows:—

Kind of coke examined.	Percentage of nitrogen found.
(a) Ordinary gas-retort (mean of two experiments) .....	1.375
(b) Beehive metallurgical coke (mean of two experiments) .....	0.511
(c) Metallurgical coke from the Simon-Carvès coke-ovens mean of three experiments) .....	0.384

From the above results it may be concluded that in (a) the effect of a sharp heat of short duration is shown, under the usual circumstances of gas retort work, not to be so efficacious in decomposing certain very stable nitrogen compounds so as to drive the nitrogen out of the coke, as a long-continued high temperature such as is found in (c). In (a) a charge of from 2 to 3 wts. of coal is heated for 6 hours, whereas in (c) a charge of 4 tons is heated for about 40 hours. The temperatures employed are not much unlike in (a) and (c), though on the whole the heat of the Simon-Carvès oven will be the stronger. No note was taken or inquiry made as to the *part* of the interior of the ovens from which the cokes under examination were taken. In the case of gas-retort and Simon-Carvès oven cokes no such note or inquiry is necessary, since in both cases external heat is uniformly applied to the mass of fuel disposed in a thin layer, which in the former case is arranged horizontally, in the latter vertically. With the Beehive coke, certain differences of temperature might occur in different parts of the mass, e.g., the portions of coke lying nearer the surface of the mass in the ordinary Beehive, and nearer the small air inlet, but not necessarily nearer the walls (not externally heated, but rather cooled), might be expected to have been more strongly heated than those lying next the floor of the oven. In the Jameson oven the temperature throughout the coking and coked mass will be much more uniform than in the ordinary Beehive. In the above-mentioned experiments, simply a well-burned sample of Beehive coke was taken for examination, exhibiting an average appearance and texture.—W. S.

*On the Examination of Petroleum.* Dingl. Polyt. Journ. 250 [4], 169-172. See this Journal III. [3], pages 161-162.

BEILSTEIN recommends the following process for testing the flashing point of petroleum (Fig. 1). A cylindrical

Fig. 1.

glass vessel of 35mm. diameter and 175mm length has two marks, one 60mm. from the bottom, the other 70mm. from the bottom. Petroleum oil is poured into the vessel till its level reaches the first mark. Air is conducted from a gasometer by means of an indiarubber ball-syringe attached to a fine brass tube *c*, terminating in a rose perforated with fine holes. The bulb of the thermometer *t* reaches to the middle of the oil. The apparatus is placed in a water bath, the temperature of which rises slowly 1° in from 2 to 3 minutes. Each time, when the temperature of the petroleum has increased about 1°, air is passed through for 5 seconds, and so quickly that the foam reaches up to the second mark on the glass vessel. At the same time a small flame is held at the mouth of the apparatus. (See pp. 161-162 of this Journal). The apparatus (Fig. 2) of Alex. Ehrenberg, of Dresden, is constructed on the syringe principle, and consists of

two limbs, A and B, combined together at E. The one contains the piston and the other the thermometer C. From the stem B a tube D leads to the ignition flame *a*. For use the apparatus is filled with the petroleum to be tested, and warmed or cooled down in the water bath till the

Fig. 2.

thermometer C indicates the experimental temperature. Then the piston is forced down, and thus a portion of the oil gases are carried to the flame. After again raising the piston rod, the experiment can be repeated until the flashing point be discovered.—W. S.

*Obtaining Ammonia, Tarry Matters, and Combustible Gases from Coal.* L. Mond, Northwich. Eng. Pat. 3923, August 13, 1883.

THE inventor has found that in the combustion of coal in gas producers a low and not a high temperature, as generally supposed, is most conducive to the formation of ammonia from the nitrogen contained in the coal. Nearly the whole of the nitrogen contained in the coal is obtained as ammonia, if the fuel be burned in the presence of steam at a temperature below the point of dissociation. To effect this a limited supply of air, loaded with water spray or steam in large quantity is introduced into the furnace. The resulting gases are richer in hydrogen and have a higher heating power, and the tarry matter is also richer and larger in quantity. The temperature may be also kept low by the use of air partly deprived of oxygen, *e.g.*, furnace gases. The ammonia and tar are collected by cooling and condensing, or the ammonia may be absorbed without cooling by a solution of calcium chloride or magnesium chloride, or by sulphuric acid. The point of novelty claimed is the employment of a low temperature of combustion by loading or charging the limited supply of air with so large an excess of steam or water that the temperature of combustion does not exceed a dull red heat.—C.C.H.

*Improvements in the Mode of Refining Paraffin.* C. Crellin, Leytonstone. Eng. Pat. 3717, 1883.

THE paraffin is melted and treated several times with sulphuric acid. It is then separated and mixed with fuller's earth at a temperature of about 180° F. This treatment is repeated at a temperature of 220° F., when the separated paraffin will be a lightly-refined wax.—A. H. A.

*Process of and Apparatus for Distilling Peat and Obtaining By-products therefrom.* F. C. Glaser, Berlin. Eng. Pat. 3855, 1883.

THIS invention has received provisional protection only. It relates to a process by means of which combustible matter in peat is converted into gaseous fuel for heating purposes, whilst at the same time the by-products, such

as ammonia, pyroligneous acid, tar, and hot air are obtained therefrom much more effectually than hitherto. The essential feature of success consists in so carrying out the operations as to carefully avoid the attainment of any high degree of heat.—D. B.

*Improvements in the Treatment of Bituminous Shales largely impregnated with Sulphur, and in obtaining Products therefrom.* C. Maclaren Irvine, Blackwood, and R. Slater, London. Eng. Pat. 3725, 1883.

THIS invention has for its object the distillation of shales containing large quantities of sulphur, the utilisation of the sulphuretted compounds given off during the distillation, and the prevention of nuisance. The shales are distilled at a low heat, with or without the application of steam, the watery and oily distillates being condensed in the usual manner, whilst the gases generated, consisting of hydrocarbons and sulphur compounds, are treated as follows: They are either simply burnt, and the resulting sulphurous anhydride is used for the manufacture of sulphuric acid, or sulphurous acid in a gaseous state, or in solution in water, is mixed with the gases or with sulphurous acid gas and steam, the result being the formation of water and elimination of sulphur. By adopting the latter method the gaseous hydrocarbons are at the same time purified, and can be utilised for heating or lighting purposes. The inventors also employ oxides of iron such as are used for the purification of coal gas, the resulting product being employed for the manufacture of sulphuric acid.—D. B.

#### IV.—COLOURING MATTERS AND DYES.

*On a Blue Colouring Matter from Pyrrol.* G. L. Ciamician and P. Silber. Berl. Ber. 17, 142.

THE discovery by Victor Meyer of the formation of a blue colouring matter by the action of isatin on thiophene, and the analogous behaviour of pyromucic acid, induced the authors to ascertain whether pyrrol would give a similar reaction. The colouring matter obtained by them appeared to be formed not like that of indophenin from isatin and thiophene, but by the union of a double molecule of isatin with two molecules of pyrrol, with liberation of one molecule of water, thus—

Two parts of isatin were dissolved in 50 parts of glacial acetic acid—pyrrol being partly decomposed by mineral acids—and 1 part of pyrrol was added to the boiling liquid. The liquid became dark blue at once, and was poured into water. The colouring matter was precipitated by the addition of sodium carbonate until the solution was nearly neutral, and the fine dark blue powder was filtered. After washing repeatedly with water, and drying, it was recrystallised from hot glacial acetic acid and then from alcohol. The crystalline structure of the dark blue powder was seen under the microscope. The analyses of the substance agreed fairly well with the formula  $C_{24}H_{18}N_4O_3$ , but the authors are not sure of its correctness, and are attempting to obtain confirmation of it. The colouring matter is soluble in glacial acetic acid, phenol, boiling alcohol, and concentrated sulphuric acid, but the latter solution becomes discoloured and deposits a black powder. The colouring matter is insoluble in ether. Its solution in acetic acid is decolourised by zinc dust.—S. Y.

*On Indophenols and Colouring Matters resembling Indophenols.* Richard Möhlau. Berl. Ber. 16, 2843.

THE beautiful brown colouring matters obtained by Hirsch, Schmitt and Andresen, Witt, and others, which contain the common trivalent group  $>N-O-$  may be divided into two groups, those which resemble indophenols, and indophenols. According to the author the term "indophenol" should be applied to the former class of substances, since they possess the properties of phenols; for the latter he proposes the name "indoaniles," because they are formed from derivatives of aniline.

I. COLOURING MATTERS RESEMBLING INDOPHENOLS.

(*Indophenols*): These relatively unstable compounds may be obtained by four methods: (a) By the action of quinone chlorimides on alkaline solutions of certain phenols at the ordinary temperature, whereby blue alkali salts are formed which dissolve in alcohol with a fuchsin-red colour. (b) By oxidation of an alkaline solution of equal molecules of a paramidophenol and a phenol. (c) By the action of quinone chlorimides on phenols between 20° and 100°, when the substances corresponding to the blue alkali salts are formed. (d) By the oxidation of a solution of equal molecules of a paramidophenol and a phenol in acetic acid, by means of chromic acid. According to Hirsch the action of a quinone chlorimide on a phenol may be represented by the equation

but he did not succeed in obtaining conclusive proof of its correctness. The fact that the tendency of a substance to crystallise is increased by the introduction of electro-negative atoms or groups rendered it probable that more stable substances might be prepared by substituting chlorinated or brominated chlorimides for the quinone chlorimides, and the author therefore arranged with Herr Hirsch to investigate the action of dibromoquinone chlorimide on phenols. *Dibromoquinone Chlorimide*: By the reduction of dibromoparanitrophenol with tin and hydrochloric acid the tin double salt of dibromoparamidophenol hydrochloride was obtained in colourless prismatic needles, and after recrystallisation from dilute hydrochloric acid was added gradually to an acidified 10 per cent. aqueous solution of calcium hypochlorite, whereby the double salt of dibromoquinonechlorimide was obtained almost quantitatively in the form of clear yellow or flesh coloured crystals. These were recrystallised from glacial acetic acid, and were found to melt at 80° and to decompose at 121°. The formation of the sodium salt of dibromoquinone phenolimide was best effected by introducing gradually and with agitation 5grms. of the chlorimide, triturated with dilute alcohol, into 8c.c. to 12c.c. of an alkaline solution of phenol containing 2grms. phenol to the cubic centimetre. The blue colouring matter was at once formed, and was deposited in gold-green glittering crystals, which were collected on the filter and washed with a semi-saturated solution of common salt. The aqueous solution of the crude product, saturated at 80°, was filtered, treated with one-third of its volume of caustic soda of specific gravity 1.29, and then with so much concentrated solution of tartaric acid that the blue colour just disappeared on warming. It was then quickly filtered, and exposed to the air in shallow vessels. The long prisms obtained in this manner appear gold-green by reflected and blue by transmitted light. They dissolve in water and alcohol with a pure blue colour. The formula

was confirmed by analysis. The blue colour of the solution disappears on warming with dilute caustic soda, but reappears on standing in contact with the air. Since neither the formation of a leuco compound nor the decomposition of the substance into dibromamidophenol and phenol can take place, the author offers an explanation of the reaction by assuming the formation of a substituted hydroxylamine, thus—

Dibromoquinone phenolimide is best obtained from the sodium salt by the gradual addition of acetic acid to its aqueous solution at 60°. It crystallises in deep red, almost black, prisms, which possess a metallic lustre. The substance dissolves in alcohol, ether, and glacial acetic acid with a fuchsin-red colour. It is insoluble in water. Concentrated mineral acids decompose the substance with for-

mation of dibromopara-amidophenol and quinone. This appears to take place in two stages, thus—

*Leucodibromoquinone Phenolimide*: The sodium salt obtained by the action of tartaric acid on the alkaline solution is very soluble and easily oxidised. It is therefore difficult to isolate, but the leuco compound itself is easily prepared in the form of colourless prisms by passing a current of sulphur dioxide into a warm aqueous solution of the sodium salt. It dissolves in the ordinary solvents with the exception of water, and melts at 170°, becoming at the same time dark coloured. It remains unaltered in dry air. The formula

was confirmed by analysis. It appears that the hydrogen atom of the phenol which occupies the para position with regard to the hydroxyl is eliminated by the chlorine of the chlorimide, so that the hydroxyl and nitrogen take the para position in the molecule of the dibromoquinone phenolimide. This view is supported both by the action of mineral acids on the substance and by the various colour reactions which are observed when the dibromoquinone chlorimide is treated with alkaline solutions of other phenols. Of the products thus obtained the majority may be crystallised. The identity of the substances obtained by methods (a) and (b), described above, was first proved by Köchlin and Witt (D. R.-P., No. 15915). In this case the reduction product of dibromoquinone chlorimide, dibromamidophenol, is employed, and the oxidation is effected by means of potassium bichromate or ferricyanide. The formation of dibromoquinone phenolimide may be represented thus—

and

A solution of 26grms. dibromamidophenol and 10grms. phenol in 40grms. caustic soda of specific gravity 1.29 and about the same volume of water absorbs oxygen from the air with formation of the colouring matter. The oxidation is best effected with potassium bichromate at the ordinary temperature. The action is allowed to proceed until phenol can no longer be recognised. The substance is purified as described above. The methods (c) and (d) are not available in practice, for the decomposition of the substance occurs simultaneously with its formation.

2. *INDOPHENOLS*.—*Indoanilines*: These blue colouring matters differ from those described under (1), in their inability to form soluble salts with ammonia and alkalis, and especially in that they exhibit basic properties, due to the presence in the molecule of the tertiary amido group  $\text{N}(\text{CH}_3)_2$ . Two representatives of the group, phenol blue and  $\alpha$ -naphthol-blue, are described in the patent to which reference has been made. Both substances are obtained by two methods. (a) By the action of nitrosodimethylaniline on an alkaline solution of phenol and of  $\alpha$ -naphthol, especially in presence of reducing agents such as zinc dust or tartaric acid. According to the discoverers the reactions are thus represented—

and

(b) By the oxidation of an alkaline solution of equal molecules of dimethylparaphenylenediamine, and of phenol and  $\alpha$ -naphthol respectively at the ordinary temperature, thus—

and

Trichloroquinonedimethylanilenimide, prepared by Schmitt and Andresen about the same time that Köchlin and Witt discovered the indophenols, is formed by the action of trichloroquinonechlorimide on dimethylaniline, thus—

These three substances resemble each other in their stability in presence of alkalis in the cold, and in the ease with which they are decomposed by concentrated acids. The structural formula of the trichloro compound is certainly

and it may be derived from phenol blue, which would then be benzoquinonedimethylanilenimide

while  $\alpha$ -naphthol blue would be  $\alpha$ -naphthoquinonedimethylanilenimide

Although no direct proof of the constitution of these compounds has been obtained by the author, the following observations support this view of their structure: In the specification of the patent it is stated that the indophenols dissolve in dilute acids, but that the solution decomposes, after a short time, with the formation of a mixture of brown substances. An investigation of the action of moderately-concentrated hydrochloric acid on some indophenol paste, obtained from H. A. Schlieper, in Elberfeld, and prepared by Messrs. L. Casella and Company, in Frankfort-on-Maine, and which proved to be  $\alpha$ -naphthol blue, showed that the substance splits up into  $\alpha$ -naphthoquinone and dimethylparaphenylenediamine. Similarly the decomposition products of phenol blue were found to be benzoquinone and dimethylparaphenylenediamine. The reactions which take place may be expressed thus—

$\alpha$ -naphthol blue. The formation of  $\alpha$ -naphthol blue from dimethylparaphenylenediamine would then take place as below:—

and similarly with phenol blue. In connection with this subject, the preparation of  $\alpha$ -naphthol blue from Biedermann's dibromo- $\alpha$ -naphthol and dimethylparaphenylenediamine, patented by L. Casella and Company, (III. Zusatz patent zu D. R.-P. 15915) is of considerable theoretical interest. The constitution of the dibromo- $\alpha$ -naphthol is probably

because (1) it yields phthalic acid on oxidation, so that the bromine atoms must be in the same benzene ring,

and (2) it is formed by direct bromination like dibromophenol, which has the structure

The formation of  $\alpha$ -naphthol blue probably takes place as follows: The bromine atom occupying the para position with regard to the hydroxyl unites with a hydrogen atom of the amido group in the molecule of the dimethylparaphenylenediamine, liberating hydrobromic acid and forming the compound

An alteration in position of the atoms may then be assumed to occur thus—

while lastly, hydrobromic acid is set free, and  $\alpha$ -naphthol blue

is formed. The relation between the substances resembling safranines and indophenols is shown by the action of caustic soda on Bindschelder's dimethylphenylene green, whereby phenol blue and diamethylamine are formed, thus—

It appears probable that diphenylamine, diphenylhydro-sulfamine and phenyl- $\alpha$ -naphthalamine are related to the substances resembling indophenols, the indophenols, the group to which methylene blue belongs, the safranines, aniline black, and the indulines, in the same way that triphenylmethane and its homologues are related to the rosaniline, rosolic acid, and phthalein group. Thus leucodibromoquinonophenolimide may be considered as diparaoxydibromodiphenylamine—

the leuco-compound of phenol blue or phenol white as dimethylparamidoparaoxydiphenylamine—

$\alpha$ -naphthol white as dimethylparamidoparaoxyphenyl- $\alpha$ -naphthylamine—

leucotrichloroquinonedimethylanilenimide as dimethylpara(?)amidoparaoxytrichlorodiphenylamine

leucodimethylphenylene green as tetramethyldiparamido diphenylamine

and leucomethylene blue or methylene white as tetramethyldiparamidodiphenylhydrosulphamine

The comparative facility with which diphenylamine and similar amido compounds may be prepared on the large scale makes it extremely probable that they will play an important part in the manufacture of colouring matters.—S. Y.

*On Azo and Disazo Compounds of the Cresols.* E. Nölting and O. Kohn. Berl. Ber. 17, 351.

WITH the exception of a paper by Mazzara, on phenylazoparacresol,

and a note by Stebbins, on phenylazocresolsulphonic acid, no work on the azo compounds of the cresols has been published. The experiments to be described show that paracresol combines with diazo compounds with as much ease as ortho- or metacresol. In the compounds formed the diazo group takes the ortho position with respect to the hydroxyl of the cresol. Neither diazo compounds nor nitroso compounds were obtained from paracresol. In the combination of ortho and metacresol with diazo compounds the azo group takes the para position with respect to the hydroxyl. Diazo compounds are readily formed from ortho and metacresol, and in these compounds, just as in the phenyldiazophenol prepared by Griess, the two azo groups occupy the ortho and para position with regard to the hydroxyl, and therefore the meta position with respect to each other. Nitroso compounds are also readily formed, the nitroso, like the azo group, taking the para position.

1. AZO COMPOUNDS OF PARACRESOL.—Phenylazoparacresol

The method of preparation described by Mazzara was modified, in so far that diazobenzene chloride was first prepared and poured into a concentrated alkaline solution of paracresol. Both liquids were cooled by the addition of ice. The quantities of the substances employed were: aniline, 20grms.; 30 per cent. hydrochloric acid, 52grms.; water, 400—450c.c.; titrated solution of sodium nitrate, equivalent to 15grms.  $\text{NaNO}_2$ ; paracresol, 22grms., dissolved in excess of caustic soda and diluted to 500c.c. An orange-yellow precipitate of phenylazoparacresol formed at once, and increased on standing. It was filtered after 24 hours, and after recrystallisation from benzene, or benzene and ligroin, was obtained in beautiful orange-yellow leaflets, melting, like Mazzara's product, at  $108^\circ$  to  $109^\circ$ . The composition was confirmed by analysis. Acids precipitate the substance unaltered from its alkaline solution. The yield is almost the theoretical. The substance dissolves with difficulty in concentrated, but easily in dilute warm alkalis. All attempts to prepare a disazo compound were fruitless. Phenylazopara-acetylresol

was prepared by heating phenylazoparacresol with slight excess of acetyl chloride or anhydride. The substance crystallises from dilute alcohol in fine yellow needles, melting at  $67^\circ$  to  $68^\circ$ . It is easily soluble in cold alcohol, ether, chloroform, and acetone. It is saponified slowly by carbonates, more rapidly by alkalis, but best by alcoholic hydrochloric acid, phenylazoparacresol being re-formed. The substance was analysed. The benzoyl compound

was prepared from benzoyl chloride dissolved in ether or benzene. It forms yellow needles, melting at  $113^\circ$ , easily soluble in boiling but with difficulty in cold alkalis; readily soluble in ether, chloroform, and hydro-

carbons. It is saponified with difficulty by alkalis. Azobenzene-azoparacresol

is not quite so easily prepared as the corresponding aniline compound. To a solution of amidoazobenzene hydrochloride in a little alcohol another molecule of hydrochloric acid was added, and the mixture poured into water, and treated, while cooled with ice and agitated, with sodium nitrite. After standing for some time the diazo compound was poured into a cooled alkaline solution of paracresol. After some hours the mixture was warmed. The azo compound was deposited, and was recrystallised from glacial acetic acid. It forms small brown needles, melting at  $160^\circ$ , soluble with difficulty in alcohol, more easily in chloroform and hydrocarbons, and readily in hot glacial acetic acid. It is not dissolved by alkalis, but forms a red-violet solution with sulphuric acid. It was analysed. Paratolylazoparacresol

was prepared like the phenyl compound. It crystallises from toluene in reddish crystals or in yellow tablets, which melt at  $112^\circ$  to  $113^\circ$ . Difficultly soluble in cold, easily in hot alcohol, and in ether, chloroform, and hydrocarbons. The acetyl compound was obtained in yellow needles, melting at  $91^\circ$ , while the benzoyl compound melted at  $95^\circ$ . The same azocresol was prepared from Witt and Nölting's amidoazoparacresol, the constitution of which is known, hence the formula given is confirmed. Parasulphophenylazoparacresol

was formed by the action of diazobenzene sulphonic acid on an alkaline solution of paracresol. 8grms. of caustic soda, 32grms. of sulphanilic acid, and 12.1 grms. of sodium nitrite were dissolved in 200c.c. to 300c.c. of water, and to the cooled solution 43grms. to 45grms. of 30 per cent. hydrochloric acid were added. After standing a quarter of an hour the mixture was poured into a concentrated alkaline solution of 20grms. of paracresol. The acid sodium salt was precipitated from the dark yellowish-red solution by the addition of hydrochloric acid. After recrystallisation the free acid was prepared from the saturated aqueous solution by the addition of concentrated hydrochloric acid. It forms yellow-brown leaflets, which reflect violet light. It is easily soluble in cold water, moderately so in boiling alcohol, but almost insoluble in cold. It decomposes on heating. A number of well-crystallised salts were obtained. The acid potassium salt

forms beautiful yellow leaflets, and is soluble in cold water. The corresponding sodium salt is very similar. The acid magnesium salt forms yellow-brown leaflets, which are insoluble in cold but dissolve easily in boiling water. The acid barium salt forms yellow-brown tabular crystals, insoluble in cold and but slightly soluble in hot water. The free acid and the acid solutions of its salts colour silk and wool a beautiful yellow, the tint being more orange than the corresponding phenol compounds. The same sulphonic acid was prepared by dissolving phenylazoparacresol in 4 to 5 times its weight of 100 per cent. sulphuric acid, and adding fuming sulphuric acid containing 60 to 65 per cent. of  $\text{SO}_3$ , in the proportion of one molecule  $\text{SO}_3$  to one of the cresol. The mixture was warmed until a drop of it gave a clear solution with water, when the free acid was precipitated by pouring into a small quantity of water. The properties of both the free acid and its salts were identical with those of the compounds just described, and their identity was further proved by the formation of sulphanilic acid by the reduction of the acid. Phenylazoparacresolsulphonic acid

When paracresol is treated with ordinary sulphuric acid, the sulphonic acid

is formed. It unites readily with diazo compounds, forming colouring matters soluble in water. The above compound was formed by its union with diazobenzene-chloride. It was obtained after recrystallisation in small red-brown tablets or needles, easily soluble in cold water, but with difficulty in alcohol. The acid sodium salt forms red-brown scales, readily soluble in hot and moderately in cold water. The acid solution imparts to wool and silk the same colour as the isomeric compound from sulphanilic acid. Neither diazobenzene chloride nor diazobenzene sulphonic acid combines with the paracresol disulphonic acid prepared by Engelhardt and Latschinoff, which the authors, by converting it into the corresponding dinitro compound, found to possess the constitution

Metasulphoparatolylazoparacresol

was prepared from the diazo compound of paratoluidine-sulphonic acid

in the same way as the compound from sulphanilic acid. It forms red-brown crystals, which reflect violet light strongly. It dissolves easily in water, but with difficulty in alcohol. The acid sodium and barium salts were prepared. The sodium salt forms yellow scales soluble in cold water. The barium salt crystallises from dilute hydrochloric acid in small red-brown needles, almost insoluble in cold and but slightly in hot water.

**Reduction of Azoparacresol Compounds:** This was carried out with tin and hydrochloric acid, or with an acid solution of stannous chloride. The products obtained from phenylazoparacresol were aniline and amidoparacresol. Though the separation of these products was not easy, yet the quantity of the amidoazoparacresol was sufficient to establish its identity with that obtained from the sulphanilic acid. Since the same amidoresol was always obtained, the authors conclude that only a single azo compound is formed by the union of diazo compounds with paracresol. The free acid or the barium salts was warmed on the water-bath with tin and hydrochloric acid, or with an acid solution of stannous chloride, until the yellow colour had disappeared. After evaporation to a small bulk, the sulphanilic acid or barium salt was filtered, the filtrate diluted with water, the tin precipitated with sulphuretted hydrogen, and the liquid evaporated in a current of sulphuretted hydrogen. The amidoresol was then precipitated from the concentrated solution with sodium carbonate. The mother-liquor contained small quantities of amidoresol, which was extracted with ether. The amidoresol was rapidly filtered, dried in vacuo over sulphuric acid, dissolved in absolute ether, and precipitated with hydrochloric acid. The chloride was filtered, drained, and washed with absolute ether. It was thus obtained as a white powder, which was quite stable even in the air. The operations must be conducted quickly, for the amidoresol and the hydrochloride, when impure or in solution, readily form tarry compounds. The chloride is easily soluble in water and alcohol, but insoluble in absolute ether and benzene. It begins to sublime on the water bath. Ferric chloride colours its aqueous solution red, but gives no such reaction with free amidoresol. The substance was analysed. Amidoresol

was precipitated from the chloride with sodium bi-

carbonate, and crystallised from ether or benzene. It forms glittering white scales, melting at 135°, which are stable in the air. It is easily soluble in alcohol, ether, and chloroform, but much less so in hydrocarbons and in water. It sublimes in white scales or needles, which melt at 135°. The composition was confirmed by analysis, and its constitution was proved by a comparison of its properties with those of the two possible amidoresols. It was found to be identical with the ortho-amido compound ( $\text{OH} : \text{NH}_2 = 1 : 2$ ) investigated by Wagner, Hofmann, and Miller. The same compound was prepared by the authors from the nitroparacresol, melting at 34°. The methenyl and ethenyl compounds were prepared. Ethenylamidoparacresol

was obtained by heating amidoparacresol-chloride with excess of acetic anhydride and anhydrous sodium acetate for several hours in a flask with a reversed condenser. The compound boiled after repeated distillation at 218°–219°. It possesses a characteristic odour, and it is difficultly soluble in water, but easily in alcohol and ether. It is soluble in acids, but the salts are unstable and liberate the free base. On heating they yield acetyl-amidoresol. The chloride and chloroplatinate were prepared and analysed. Acetylamidoparacresol

is easily obtained by warming a solution of the ethenyl base in dilute sulphuric acid, in the form of long white needles. After recrystallisation from water the substance melted at 159°–160°. It is very slightly soluble in water, alcohol, benzene, and ether in the cold, but more so on heating. The substance was analysed. The constitution of the amidoresol is thus confirmed. The isomeric compound

melts at 143°–144°. **Constitution of Azoparacresol Compounds:** It follows from the experiments described that in the azo compounds of paracresol the azo group occupies the ortho position with regard to the hydroxyl, just as in the derivatives of  $\beta$ -naphthol described by Liebermann and Jacobsen (*Berl. Ber.* 14, 1310 and 1791). The authors also succeeded in preparing paratolylazoparacresol from amidoazoparatolol, but the yield was very small. The amido group in amidoazo compounds seems thus to be much less easily replaced by hydroxyl than in the amines, for with the latter very good results are obtained. The formation of paratolylazoparacresol is a further proof of the constitution of the azoparacresol compounds. The structure of these compounds is thus represented—

does not combine with diazo compounds.

2. AZO COMPOUNDS OF ORTHOCRESOL.—When diazobenzene chloride was added to an alkaline solution of

ortho-cresol, only a small precipitate was formed. The phenylazo-ortho-cresol

was precipitated with an acid and recrystallised from a mixture of benzene and ligroin or dilute alcohol. It forms beautiful yellow glittering scales, melting at  $129^\circ$ – $130^\circ$ , insoluble in cold, difficultly in boiling water, easily soluble in alcohol, ether, chloroform and hydrocarbons, but less so in ligroin. Like phenylazophenol it has still feeble acid properties: it does not decompose carbonates, but dissolves in cold dilute alkalis and ammonia with a yellow-red colour. The lead salt was prepared. The composition was proved by analysis. The product precipitated in small quantity directly from the alkaline solution consisted of a mixture of the sodium salt of phenylazo-ortho-cresol and phenyldisazo-ortho-cresol. It was treated with dilute acid, and then with cold alcohol, in which the azo compound dissolves readily, while the disazo compound is almost insoluble. By recrystallisation from hot alcohol phenyldisazo-ortho-cresol

was obtained in red-brown scales, melting at  $114^\circ$ – $115^\circ$ , difficultly soluble in cold, more easily in boiling alcohol, but generally less soluble than the azo compound. With warm alkalis it forms a yellowish-red solution, but it is insoluble in carbonates and in ammonia. It forms a red solution with cold sulphuric acid. The same substance is more easily prepared by the action of two molecules of diazobenzene chloride on an alkaline solution of ortho-cresol. The greater part separates at once—the rest is precipitated by the addition of an acid. The azo compound is frequently formed as well as the disazo compound. The composition was confirmed by analysis. An acetyl compound may be prepared in the usual way: it crystallises from dilute alcohol in beautiful yellow needles, which melt at  $120^\circ$ – $121^\circ$ , and dissolve easily in cold alcohol, ether, and benzene. When heated with alkalis or hydrochloric acid the original substance is re-formed. Phenylazo-ortho-acetylcresol

is obtained by heating the azo compound with acetic anhydride or chloride. It crystallises from dilute alcohol in beautiful yellow tablets, melting at  $81^\circ$ – $82^\circ$ , and moderately soluble in cold alcohol, ether, chloroform, and aromatic hydrocarbons. It is saponified with difficulty by carbonates, more easily by dilute alkalis or alcoholic hydrochloric acid. The substance was analysed. The corresponding benzoyl compound forms small yellow needles, which melt at  $110^\circ$ – $111^\circ$ , and dissolve with difficulty in cold but readily in boiling alcohol, also in ether, chloroform, and acetone. It is not saponified by carbonates, and very slowly by alkalis. It was analysed. Parasulphophenylazo-ortho-cresol

was prepared like the corresponding compound from paracresol. The free acid crystallises from very dilute hydrochloric acid in small red-brown needles, soluble with difficulty in cold, easily in hot water, and almost insoluble in alcohol. The acid sodium and barium salts were prepared and analysed. *Reduction of Azo-ortho-cresol Compounds:* It was to be expected that in the reduction of these compounds the amido group in the amido-cresol would occupy the para position with regard to the hydroxyl, and this was found to be the case. The method of reduction was the same as in the previous case. The amido-cresol crystallised from benzene in small white scales, which melted at  $172^\circ$ – $173^\circ$ . After sublimation the melting point was  $174^\circ$ – $175^\circ$ . It is easily soluble in alcohol and ether, less so in water and hydrocarbons. By its oxidation with chromic acid toluquinone, melting at  $67^\circ$ – $68^\circ$ , was formed, and the constitution was thus proved. The same amido-cresol was

obtained by the authors by reduction of nitroso-ortho-cresol, in which the nitroso group was known to occupy the para position. By treating an ethereal solution of the base with gaseous hydrochloric acid, amido-ortho-cresol hydrochloride

was precipitated as a white crystalline powder, easily soluble in water and alcohol. It is not coloured by ferric chloride, but on warming the solution quinone is formed. The hydrochloride was analysed.

3. AZO COMPOUNDS OF METACRESOL.—Phenylazo-metacresol

By the action of diazobenzene chloride on an alkaline solution of metacresol, an insoluble precipitate and a highly-coloured solution were obtained. The precipitate consisted chiefly of the disazo compound, while the azo compound was contained in the solution, and was separated and purified in the usual way. It crystallises from ligroin in beautiful yellow needles, melting at  $109^\circ$ . It is easily soluble in alcohol, ether, chloroform, and hydrocarbons. It forms yellowish-red salts with alkalis and ammonia, but does not decompose carbonates. The composition was confirmed by analysis. Sulpho-orthotolyl-azometacresol—

was obtained in the usual way from metacresol and the sulphonic acid of orthotoluidine prepared by Neville and Winther. The free acid forms small red-brown crystals, which reflect violet light. It dissolves readily in cold water, less so in cold but easily in hot alcohol. The acid sodium and barium salts were prepared and analysed. The former is easily soluble in water, the latter almost insoluble in cold but moderately soluble in boiling water. The azo compounds of ortho- and meta-cresol colour silk and wool an orange-yellow. *Reduction of Azometacresol Compounds:* An amidometacresol was obtained in the usual way. It melted at  $151^\circ$ , and yielded a toluquinone melting at  $67^\circ$  to  $68^\circ$ . Its constitution must therefore be—

and the azo group therefore occupies the para position with respect to the hydroxyl in the azo compounds of metacresol. Phenyldisazometacresol

The insoluble precipitate mentioned above was purified in the same manner as the corresponding compound from ortho-cresol. The same compound was prepared by adding two molecules of diazobenzene to an alkaline solution of metacresol. It crystallises from alcohol in red-brown scales, melting at  $149^\circ$ . In this case, again, the melting point of the disazo is higher than that of the azo compound. It is difficultly soluble in cold, more easily in boiling alcohol; soluble in ether, chloroform, and benzene. It dissolves in warm dilute caustic potash. The composition was proved by analysis. The acetyl compound was also prepared. It crystallises from dilute alcohol in small yellow-brown needles, melting at  $156^\circ$  to  $157^\circ$ . *Constitution of the Disazo Compounds of the Phenols and Cresols:* The reduction of these compounds to the corresponding diamines offers the best means of determining the position of the second azo group. The diamido phenols are very unstable, but their ethers are less easily decomposed. Both the alcoholic and acid ethers of the amidophenols possess the properties of amines. As the one azo group, both in the phenol and in the two cresol derivatives, occupies the para position with regard to the

hydroxyl, the second must take either the ortho or meta position, as represented by the formulæ—

and the corresponding diamines must behave as meta or orthodiamines. The first of these formulæ has been experimentally established. Phenyldisazomethylphenol,  $(C_6H_5N=N)_2C_6H_3OCH_3$ , was prepared by dissolving 3grms. of phenyldisazophenol in 20c.c. of absolute alcohol, adding 0.4grms. of potassium, and, after cessation of the evolution of hydrogen 2grms. to 2.5grms. of methyl iodide. After heating for some hours on the water bath, the alcohol was removed by evaporation, the residue freed from potassium iodide by washing with water, and the purified product recrystallised from ligroin, to which a little animal charcoal was added. The substance dissolved with difficulty in cold but easily in boiling alcohol, and in acetone, chloroform, ether, and benzene. It melts at  $110^\circ$ . Phenyldisazophenol is reproduced by warming with alkalis. The substance was analysed. The acetyl compound, prepared in the ordinary way, crystallised from alcohol in small yellow needles, melting at  $116^\circ$ , and soluble in alcohol, ether, chloroform, and benzene. It is easily saponified by alkalis or alcoholic hydrochloric acid, with difficulty by carbonates. The benzoyl compound was prepared from benzoyl chloride. It crystallises from alcohol in small yellow needles, which melt at  $138^\circ$  to  $139^\circ$ . It is not easily saponified by alkalis. *Reduction of Disazo Compounds:* The ethers of the disazo compounds were dissolved in cold glacial acetic acid, and reduced in the cold with zinc dust. The solutions were diluted with water, filtered from zinc dust, and tested directly. The presence of the primary bases is not prejudicial to the reactions of the meta, or for the most part of the para diamines. A brown coloration was produced by the addition of a nitrite to the solution acidified with a few drops of hydrochloric acid. Diazobenzene chloride produced an orange-yellow coloration, and nitrosodimethylaniline, or better dimethylphenylenediamine, and an oxidising agent gave Witt's neutral tint reaction. The two amido groups therefore occupied the meta position with regard to each other. The three ethers of phenyldisazophenol and the acetyl derivatives of both diazoeresols gave precisely the same reactions—hence the position of the amido groups is the same in all. Since paracresol forms no disazo compound, it must be concluded that one but not two azo groups can occupy the ortho position with regard to the hydroxyl.—S. Y.

*On the Oxidation of Purpurine.* Chr. Dralle. Berl. Ber. 17, 376.

It is well known that the purpurine obtained from madder is less stable than the isomeric compounds prepared synthetically, and far less so than alizarin. Selunk and Römer observed that a solution of purpurine in caustic potash lost its colour when exposed to the light. It was not known what product was found, but the author, repeating the experiment, recognised the presence of phthalic acid in the solution. Phthalic acid is also formed by the oxidation of an alkaline solution of purpurine by means of potassium ferricyanide. Quinizarin, under the same conditions, yields phthalic acid, but alizarin gives no crystalline products which can be extracted with ether.—S. Y.

*Note on Chrysaniline.* R. Auschütz. Berl. Ber. 17, 433. (The author describes experiments on chrysaniline made in conjunction with Dr. Oscar Müller.)

In order to ascertain the number of amido groups in chrysaniline the acetyl compound was prepared by heating one part of crude chrysaniline with  $2\frac{1}{2}$  parts of acetic anhydride, in sealed tubes, from  $140^\circ$  to  $160^\circ$  for 8 to 12 hours. The product, which still possessed basic proper-

ties, was poured into water, and the resinous substance boiled repeatedly with water and filtered while hot. The hydrochloride was precipitated from the filtrate by the addition of hydrochloric acid, and the acetyl compound liberated by means of caustic soda. It was almost insoluble in water, but dissolved in alcohol. From the alcoholic solution, which exhibited a blue fluorescence, the substance was precipitated in the form of microscopic needles by careful addition of water. The analysis of the compound agreed with the formula  $C_{19}H_{13}N_3(C_2H_3O)_2$ , so that there are probably two amido groups present in the molecule. The hydrochloride and nitrate of the acetyl compound were prepared and analysed. The former occurs in yellow flakes, consisting of minute long yellow needles. It is easily soluble in hot water, much more so than in dilute hydrochloric acid, by which it is saponified on heating. It dyes silk and wool yellow. The nitrate was prepared by the addition of silver nitrate to the hydrochloride. Pure chrysaniline was prepared by boiling one part of the pure acetyl compound with three parts of hydrochloric acid (of specific gravity 1.12) and six parts of water for eight hours. The residue after evaporation was dissolved in water and precipitated with nitric acid. The hot aqueous solution of the nitrate was treated with caustic soda, and the precipitated chrysaniline recrystallised from dilute alcohol, when it was obtained in prismatic needles. The analysis of the compound agreed fairly well with the formula  $C_{19}H_{15}N_3$ . The properties of chrysaniline are very little altered by its conversion into the acetyl compound. The latter possesses powerful basic properties, and forms salts which are very similar to those of chrysaniline. The hydrochloride, for instance, is a colouring matter. The author and Dr. Müller considered that the basic properties of the acetyl compound were due to the similarity in position of the third nitrogen atom to that in the molecule of pyridine or quinoline. The effect of oxidising agents on chrysaniline was therefore studied. Potassium permanganate yielded only oxalic acid, but potassium bichromate and sulphuric acid gave better results. One part of chrysaniline was dissolved in nine parts of sulphuric acid diluted with fourteen parts of water, and to the solution six parts of bichromate were gradually added. The reaction was completed by boiling the mixture a few minutes. The precipitate was filtered, dissolved in an alkali, and treated while cold with potassium permanganate so long as the red colour changed to green. After removal of excess of permanganate by boiling with alcohol the solution was filtered and precipitated with hydrochloric acid. The precipitate was dried, mixed with twenty parts of lime, and distilled. Acridine and at least two other bases were found in the distillate, but the quantity of only one of them was large enough for investigation. The hydrochloric acid solution of the distillation products was treated with ammonia, when the bases separated in the liquid state, but after standing a few days, white leafy crystals were deposited, together with brown masses. The crystals were purified by sublimation, and were found to be difficultly soluble in water, but easily in alcohol. They melted at  $148^\circ$ — $150^\circ$ . The picrate was much more easily soluble in alcohol than acridine picrate. The nature of the other substances was not ascertained, but it was thought possible that an amido-acridine might be formed by the distillation with lime of the oxidation products of chrysaniline. Amidoacridine was therefore prepared by the reduction of the nitroacridine, melting at  $215^\circ$ , with tin and hydrochloric acid. It melted at  $209^\circ$ . The picrate was a scarlet substance, soluble in cold alcohol, and crystallising from hot alcohol in garnet-red prisms, which, when examined under the microscope, were found to resemble the picrate formed from the brown masses mentioned above. S. Y.

*On Haematoxylin and Brasilin.* Chr. Dralle. Berl. Ber. 17, 372.

THE action of various reagents on haematoxylin and brasilin was studied with the view to obtain products, which might throw a light on the structure of these compounds. The results, however, were not very satis-

factory. (1) *Haematoxylin*: By heating with ten parts of concentrated hydrochloric acid, in sealed tubes, to  $110^{\circ}$  to  $115^{\circ}$ , and by the action of 40 per cent. hydrobromic acid, colourless crystals were obtained embedded in a black smeary mass, from which they could not be separated by means of any solvent. The action of chlorine gas on an aqueous solution of haematoxylin yielded no definite product. By the action of titrated chlorine water on the aqueous solution various chlorine substitution products were obtained, but they could not be crystallised. With two molecules of chlorine to one of haematoxylin a product was obtained which contained in one case 9.09 and in another 10.26 per cent. of chlorine, while monochlorohaematein requires 10.61 per cent. The following reactions probably take place:—

At the same time one molecule of chlorine forms chlorine products, while according to the above reactions only haematein should be formed. The author does not consider the product analysed to be pure monochlorohaematein. The product obtained by the action of dry chlorine on dry haematoxylin contained only 6 per cent. of chlorine, but by the action of chlorine water on the aqueous solution a product containing 17.78 of chlorine was formed. It was not, however, a definite compound. By the addition of four molecules of bromine dissolved in glacial acetic acid to a hot solution of one molecule of haematoxylin in the same substance, the solution became cherry red, and soon deposited deep-red pointed crystals, which were washed with glacial acetic acid, and then with ether, and dried quickly at  $100^{\circ}$ . They decomposed at  $120^{\circ}$ , and could not be recrystallised. The analysis agreed with the formula  $\text{C}_{16}\text{H}_{12}\text{Br}_2\text{O}_6$ . The bromine compound dissolves in dilute alkalis and in water with a brown-red colour and without decomposition. Haematoxylin is not reformed by neutralisation with sulphuric acid, hence the bromine compound is a substitution and not an addition product. No acetyl compound could be obtained from the dibromine compound; and by fusion with potash only formic and oxalic acid were formed, besides tarry and carbonaceous matters. Nitric acid gave no result. Concentrated, or better fuming, sulphuric acid gave a sulphonic acid, which was not further investigated. The action of zinc dust was found to be similar to that described by Reim, except that the evolution of carbon dioxide and of a gas burning with a blue flame was observed, as was also the presence of resorcin in the distillate. Phosphorus, hydriodic acid, methyl iodide in presence of methyl alcohol and two molecules of caustic potash, as well as ethyl iodide under the same conditions, gave no result. Diazobenzene hydrochloride added to a solution of one molecule of haematoxylin in two of caustic potash gave a yellow-brown precipitate, which contained nitrogen, and was probably haematoxylindiazobenzene, but it could not be crystallised. Other diazo compounds might, perhaps, give better results. Acetyl haematoxylin was then examined. When treated with potassium permanganate no acetyl haematein was formed, but only carbon dioxide and oxalic acid. Nitric acid and chlorine gave no results. By heating one part of acetyl haematoxylin with 3.03 parts of a 20 per cent. solution of bromine in glacial acetic acid to  $100^{\circ}$  to  $110^{\circ}$ , in sealed tubes, for 3 hours to 4 hours, crystals were obtained, which, when washed with glacial acetic acid and ether, and dried over caustic soda and then calcium chloride, gave numbers on analysis which agreed with the formula  $\text{C}_{16}\text{H}_8\text{Br}_4\text{O}_6(\text{C}_2\text{H}_3\text{O})_5$ . The yield was, however, only 15 per cent. to 20 per cent. of the theoretical amount. With 4 molecules of bromine no crystals were obtained. The product decomposes at  $118^{\circ}$  without melting. *Brasilin*: After treatment with hydrochloric acid long needles were deposited from the acetic acid solution, but they could not be recrystallised. Hydrobromic acid and sulphuric acid gave the same results as with haematoxylin. Chlorine and bromine gave no definite products. By fusion with potash, oxalic acid, formic acid, and considerable quantities of resorcin were formed. Resorcin was also formed by heating brasilin with zinc dust. It is a product of the simple distillation of brasilin (Kopp),

*Berl. Ber.* 4, 334). With methyl iodide and caustic potash—4 molecules of alkali to 1 molecule of brasilin—a brick-red compound was obtained, the spectrum of which differed widely from that of brasilin, while the reactions with ferric chloride and with alkalis were no longer observed. The alcoholic solution was fluorescent. The new substance was doubtless a methylbrasilin, but it could not be obtained sufficiently pure for analysis. Diazobenzenehydrochloride yielded a small quantity of brasilnazobenzene, which, however, could not be purified. Attempts were made to obtain acetylbrasilein from acetylbrasilin by the action of potassium manganate, nitric acid, and bromine, and by that of acetylchloride on brasilein, but without result.—S. Y.

*Improvements in Colouring Matters.* Frank Wirth, Frankfort. A communication from Messrs. Dittler and Company, Farbwerk Griesheim-am-Main, near Frankfort, Germany. Eng. Pat. 2104, April 25, 1883.

NAPHTHALENE is heated with five times its weight of concentrated sulphuric acid to a temperature of  $160^{\circ}\text{C}$ . for four hours. The mixture of naphthalene-disulphonic acids thus obtained is nitrated when cool by the addition of nine parts of nitric acid and the nitrosulphonic acids diluted and reduced, limed, and converted into sodium salts. Other methods of sulphonating, by using a smaller quantity of fuming sulphuric acid, are also mentioned. The amidosulphonic acids thus obtained are diazotised in the usual manner and combined with phenol or the naphthols, and thus produce yellow or red dyes.—R. M.

*A New or Improved Process for the Manufacture of Blue Colouring Matters Suitable for Dyeing and Printing.* Herbert John Hadden. A communication from Lembach and Schleicher, Biebrich-on-the-Rhine, Germany. Eng. Pat. 3491, July 16, 1883. Provisional protection only.

PARA-AZOBENZENE SULPHONIC ACID is combined with dimethyl-aniline so as to produce the well-known azo-sulphonic acid

The latter is dissolved in ammonia, reduced with zinc dust, filtered, the solution acidulated, and then saturated with  $\text{H}_2\text{S}$ . Oxidation is then effected by means of ferric chloride, and the colouring matter precipitated by zinc chloride.—R. M.

*Improvements in Colouring Matters.* Frank Wirth. A communication from Heinrich Baum, Höchst-on-the-Main, Germany. Eng. Pat. 3498, July 16, 1883. Provisional protection only.

WHEN alphanaphthol is treated with from one to two parts of concentrated or fuming sulphuric acid "at any temperature, and in any manner, a mixture is almost always obtained of sulpho acids, which mixture, together with diazo bodies, yields only a small percentage of useful azo colours." The reason of this, according to the inventor, is to be found in the circumstance that "alphanaphthol, as compared with the betanaphthol, forms a very constant, and difficultly soluble alphanaphthol sulphonic acid ( $\alpha\text{-C}_{10}\text{H}_7\text{OH}\cdot\text{SO}_3\text{H}$ ), which in the presence of hydrated sulphuric acid becomes sulphurised (? sulphonated), and then by further heating yields an alphanaphtholdisulpho acid, which is useless for the production of azo colours." To obviate this the inventor first converts the naphthol into its acetyl derivative by heating with acetic anhydride and then adds the theoretical quantity of sulphuric acid (or "monoehlorhydine") to form a monosulphonic acid. Two isomeric monosulphonic acids are said to be produced by this means, the one giving a soluble and the other an almost insoluble barium salt. The acid giving an easily soluble barium salt, furnishes azo dyes with the diazo compounds of the aromatic hydrocarbons. The difficultly soluble acid, on the other hand, is stated to give no useful dyes with the diazo compounds of the aromatic hydrocarbons, but with

their diazo sulphonie and carbonic acids it yields valuable crystalline products. Detailed examples are given in the specification, and the inventor adds a long list of the various azo colours produced by the two isomeric monosulphonie acids.—R. M.

*Improvements in Colouring Matter.* Frank Wirth. A communication from Heinrich Baum, Höchst-on-the-Main, Germany. Eng. Pat. 3523, July 17, 1883. Provisional protection only.

THE inventor claims the production of a betanaphthol-disulphonie acid by the following process: The potassium salt of Schäffer's betanaphtholmonosulphonie acid is mixed intimately with an equal weight of potassium pyrosulphate, and the mixture heated with strong sulphuric acid to 120° to 130° C. until completely dissolved. The temperature is then raised and maintained at 150° to 160° C. for five or six hours. Only one disulphonie acid is said to be produced, and the inventor employs this for the manufacture of azo colours in the usual way. A list of the colours produced by combination with various diazo compounds is given in the specification.—R. M.

*Improvements in Colouring Matter.* Frank Wirth. A communication from Heinrich Baum, Höchst-on-the-Main, Germany. Eng. Pat. 3527, July 17, 1883. Provisional protection only.

THESE colouring matters are produced by treating the dry haloid salts of primary, secondary, and tertiary aromatic monamines with organic acid anhydrides, the novelty of the invention being the occurrence of the reaction without the use of dehydrating agents such as  $\text{ZnCl}_2$ , etc. Thus, in the case of aniline, the dry hydrochloride is heated with  $1\frac{1}{2}$  to twice its weight of acetic anhydride, in a closed vessel, to 180° to 200° C. for twelve hours. The resinous melt is boiled with dilute sulphuric acid, allowed to cool, filtered, and the base thrown out by alkali. The hydrochloride of the base is prepared for commerce, and is a greenish-yellow dyestuff.—R. M.

*Improvements in the Manufacture of certain Sulphonic Acids.* Frank Wirth. A communication from the Colour Factory (formerly Brönner) of Frankfurt-on-the-Main, Germany. Eng. Pat. 3606, July 23, 1883.

THE object of the invention is the preparation of sulphonic acids of betanaphthol from the betadinaphthyl ether,  $\text{C}_{20}\text{H}_{12}\text{O}$ , which is obtained in the manufacture of betanaphthol. The conversion is effected by heating the ether with ordinary sulphuric acid, or with sulphuric acid containing 10 per cent. of anhydride, according as the mono- or di-sulphonic acid is required.—R. M.

*Improvements in the Production of Certain Colouring Matters applicable to Dyeing and Printing.* Thomas Holliday, Huddersfield. Eng. Pat. 3971, August 16, 1883.

THIS invention claims the employment of the fluorols and their sulphonie acids for the production of azo colours. The fluorols are combined with the diazo salts of benzene, toluene, xylene, etc., in precisely the same way as in the case of the naphthols. By the employment of fluorylamine a series of azo colours analogous to the naphthylamine compounds is said to be obtained.—R. M.

*Production of a New Solid Base by Reaction of Aldehyde and Hydrochlorate of Aniline, or their equivalents.* John Inray. A communication from the Actien Gesellschaft für Anilin-Fabrikation, Berlin. Eng. Pat. 4207, Aug. 31, 1883.

EIGHT kilos. of aniline hydrochloride are dissolved in 16 litres of water and mixed with a cold dilute solution of aldehyde. The reaction is complete in three or four days, and on evaporating the solution the hydrochloride of the new base,  $\text{C}_{18}\text{H}_{20}\text{N}_2$ , is obtained in a crude state, and is purified by precipitation with alkali. This base, when the dry hydrochloride is treated alone or in the presence of metallic chlorides, is converted into the hydrochloride

of quinaldine. Instead of aldehyde, paraldehyde, aldol, acetal- or croton- aldehyde can be used, and the aniline may be replaced by other aromatic bases. In the ordinary preparation of quinaldine, aldehyde is made to act upon a hot solution of aniline in the presence of hydrochloric acid.—R. M.

*An Improvement in the Manufacture of Sulphoconjugate Paris Violet Dyes.* John Inray. A communication from the Société Anonyme des Matières Colorantes et Produits Chimiques de Saint Denis. Messrs. A. Poirrier and A. Rosenstiehl, Paris. Eng. Pat. 903, Jan. 7, 1884.

IN order to avoid the large excess of sulphuric acid which has hitherto been employed in preparing the sulpho acid of the Paris violets the inventors produce "from the sulphuric acid in whole or in part soluble sulphates" such as those of potassium, sodium, magnesium, zinc, etc., "no more water being added than is necessary to form a paste of suitable consistence. By this treatment there is no alteration of the colouring matter, and it is obtained in a state in which, by reason of its great solubility, it can be employed with great facility."—R. M.

I. *On Orthonitrobenzyl Chloride.* Communications by E. Nölting, Berl. Ber. 17, 385.

BEILSTEIN and Geitner observed that in the nitration of benzyl chloride, in addition to crystallised paranitrobenzyl chloride, an oil was formed, which appeared, from its analysis, to be an isomeric compound. Having some quantity of this oil at his disposal, the author subjected it to oxidation by means of potassium permanganate, and obtained, besides some benzoic acid and paranitrobenzoic acid, a large quantity of orthonitrobenzoic acid. After removal of benzoic acid with steam, the separation of the ortho and para compounds was easy on account of their different solubility, as well as that of their barium salts. The presence of metanitrobenzoic acid was not observed. The ortho compound was recognised by its melting point, and by the properties and analysis of its barium salt. At 15°, according to Strakosch, the product is almost entirely paranitrobenzyl chloride. At ordinary temperatures a considerable quantity of the ortho compound is formed. Since the nitrobenzyl chlorides are much more easily oxidised by permanganate than the nitrotoluenes, they form a convenient starting point in the preparation of para- and ortho- nitrobenzoic acid. Some attempts to prepare orthonitrobenzaldehyde from the oil were unsuccessful. [For communication II, see under Destructive Distillation, etc.] III. *On the Constitution of Phthalyl Chloride* (by the author and G. von Beech): The constitution of phthalyl chloride must be represented by one of the two formulæ—

The known constitution of phthalophenone and phthalide has generally induced chemists to adopt the latter formula, but no direct proof has been adduced unless the difference observed by Graebe between the ethers obtained from phthalates and from phthalyl chloride be taken as such. The authors attempted to solve the problem by treating phthalyl chloride with mercury diphenyl. The formation of the diketone, or of phthalophenone, as represented below, should afford the required proof—

or

Unfortunately either large quantities of the original substances remained unacted on or complete decomposition took place. Phthalophenone was, however, obtained in small quantity, while no substance having the properties of an aromatic diketone was produced. The following

method gave the best results: 6 grms. of phthalyl chloride were heated with 20 grms. of mercury diphenyl, and 20 to 30 grms. of benzene in closed tubes to 150° to 160° for twelve hours. After cooling, the crystals of mercury phenylchloride were filtered off and washed with benzene, and the latter was evaporated. The residue was boiled with concentrated hydrochloric acid to destroy the mercury compounds, and to convert the unaltered phthalyl chloride into phthalic acid. The residue was boiled first with water, then with soda, and the small residue recrystallised from alcohol in presence of animal charcoal. Pure phthalophenone was thus obtained. It melted at 112°, and a comparative microcrystallographic examination by Prof. Lehmann of the product, with that obtained by the method of Friedel and Crafts, established the identity of the substances.—S. Y.

*On Nitroso-orthocresol.* E. Nölting and O. Kohn, Berl. Ber. 17, 370.

NITROSO-ORTHO-CRESOL is easily obtained by the method of Stenhouse and Groves (Ann. Chem. Pharm. 188, 360). The orthocresol was dissolved in from 30 to 40 times its quantity of water, and treated, drop by drop, in the cold with the theoretical quantity of a titrated solution of nitrosyl sulphate, the mixture being constantly stirred. After a time a gray-white precipitate of the nitroso compound was formed, while a small quantity of tarry matter collected on the surface of the liquid and was easily removed. The filtered nitrosoresol was dissolved in ammonia, purified with carbon dioxide, and poured into ice-cold dilute sulphuric acid. The substance recrystallises from benzene in light gray warty masses, and from water in long white needles. It dissolves with difficulty in cold but easily in boiling water, and in alcohol, ether, and chloroform. It is less soluble in benzene. With dilute alkalis it forms a red-brown solution, from which it is precipitated by acids as a white flocculent precipitate. It melts at 134° to 135°, being at the same time decomposed. It was analysed. The sodium salt

obtained by the action of sodium on the ethereal solution of the nitroso compound crystallises from acetone in brown needles. It dissolves easily in water and alcohol, forming red-brown needles. It deflagrates on heating, but the water of crystallisation may be removed in a desiccator containing sulphuric acid. The potassium and silver salts were also prepared. The salts of the heavy metals give with the alkali salts of the nitroso compound amorphous precipitates of various colours. By its oxidation with potassium ferricyanide, nitroso-orthocresol yielded the nitro-orthocresol melting at 94° to 95°, while with nitric acid, of specific gravity 1.33°, the dinitro-orthocresol melting at 85° to 86° was formed. By its reduction the amidoresol, melting at 174° to 175°, was formed. The same compound was also formed by the reduction of the azo compounds of orthocresol. The amido resol yielded toluylquinone on oxidation. It is thus proved, both by its oxidation and reduction, that in the nitroso-orthocresol the nitroso group occupies the para position with regard to the hydroxyl.—S. Y.

*On the Azo Colouring Matters.* G. Schultz, Berl. Ber. 17, 461.

ACCORDING to S. Pfaff, the so-called alpha-monosulphonic acid from beta-naphthol differs from the isomeric compound obtained by Schäffer, inasmuch as it does not unite with diazoxylene under ordinary conditions, i.e., in dilute solution to form an azo colouring matter, while it does unite with other diazo compounds—for instance, with diazobenzene sulphonic acid. The author finds, however, that when a concentrated solution is employed, xyleneazobeta-naphthol sulphonic acid is obtained in the form of red needles, which, like the isomeric compound, dissolve in concentrated sulphuric acid with a cherry-red colour. The colour imparted to wool is somewhat yellower than that produced by the

isomeric colouring matter from Schäffer's acid. The behaviour of the tetrazodiphenyl obtained from benzene towards the betanaphthol disulphonic acid, which forms a sodium salt insoluble in alcohol (the so-called disulphonic acid R), is very remarkable. When one molecule of a salt of tetrazodiphenyl is added to an alkaline solution of one molecule of the above-mentioned disulphonic acid, a red colouring matter is obtained, which is completely precipitated by common salt. Neither of the original substances can be detected in the filtrate. A blue substance is not formed by warming the colouring matter. With two molecules of a cold dilute alkaline solution of the betanaphthol sulphonic acid to one of tetrazodiphenyl a red colouring matter is also formed, and may be precipitated with common salt. One molecule of the disulphonic acid is present in the filtrate. When, however, the substances are mixed in the proportion last described, and warmed, a blue substance is formed, which may also be precipitated by means of common salt. In this case no disulphonic acid is present in the filtrate. The precipitate forms a blue solution with water. In evaporation a bronze-coloured mass is obtained, which also dissolves in water with a blue colour. Alkalis colour the solution red, but hydrochloric acid gives a violet precipitate, which on heating becomes blue. The substance has not yet been crystallised. Its reactions seem to indicate that it is not an ordinary azo colouring matter but a condensation product. Other diparamines of the diphenyl group behave like benzidine, yielding with the above betanaphthol-disulphonic acid azo compounds, which form violet or blue solutions. Among others, diamidofluorene, diamido-diphenyleneketone, diamidodiphenic acid, and diethoxy-diamidodiphenyl may be mentioned. That the blue colour of the compounds is not to be referred to the diphenyl group is shown by the fact that the diazo compounds of orthoamidodiphenyl, para-amidoparabromodiphenyl or paranitrodiphenyl form red colouring matters with the same disulphonic acid. When the betanaphthol disulphonic acid G, or one of the two betanaphthol-monosulphonic acids is substituted for the above disulphonic acid, only red colouring matters are formed. The formation of violet or red products is therefore dependent on the constitution, on the one hand, of the paradiamine, and, on the other, of the beta-naphthol disulphonic acid R.—S. Y.

*Quinoline and Quinaldine.* Dingl. Polyt. Jour. 250, 533. P. FRIEDLÄNDER and C. F. Gohring (Berl. Ber. 1883, 1833) find that the reaction of orthoamidobenzaldehyde with acetaldehyde, in presence of sodium hydrate, whereby quinoline is formed, is typical of a large group of such reactions. Thus orthoamidobenzaldehyde and acetone, in aqueous solution, react in the cold, on the addition of sodium hydrate, with formation of  $\alpha$ -methyl-quinoline. The process of preparing quinaldines by the action of acetaldehyde upon salts of the primary aromatic amines has been patented (Ger. Pat. 24317, 1882) by the Chem. Fabrik auf Actien, vorm. E. Schering. The reaction with aniline is expressed by the equation

The reagents employed are as follow: 100 parts aniline, 150 parts paraldehyde, 200 parts hydrochloric acid, and 3 parts aluminium chloride. These are boiled together from 4 to 6 hours, sodium hydrate is then added in excess, and the bases thereby separated are purified by fractional distillation. Quinaldine thus obtained boils at 240°; orthomethylquinaldine is a liquid boiling at 250°; paramethylquinaldine is crystalline, and melts at 60°. The hydroxy derivatives of the bases are prepared by fusing their sodium sulphonates with four times their weight of caustic soda. The corresponding methoxy and ethoxy derivatives are obtained from the hydroxy compounds by treatment with the respective iodides. Or these may be directly obtained from the amidophenols according to the typical equation

Orthoxyquinaldine crystallises in colourless needles, m.p. 72°; the para compound melts at 213°; methoxy-

quinaldine,  $\text{CH}_3\text{O}\cdot\text{C}_{10}\text{H}_8\text{N}$ , crystallises in shining prisms, m.p.  $125^\circ$ . The quinaldine bases are converted into corresponding hydro bases by reduction with tin and hydrochloric acid. These latter react with the salts of diazobenzene to form red-brown colouring matters; with benzotrichloride to form green colouring matters. L. Kuow (*Berl. Ber.* 1883, 2593) has shown that the product of the reaction of aniline with acetoacetic ether at  $120^\circ$  is converted by treatment with sulphuric acid into oxymethylquinoline. O. Döbner and W. v. Miller (*Berl. Ber.* 1883, 2465) have investigated the hydro base obtained by the action of tin and hydrochloric acid upon quinaldine. This tetrahydroquinaldine,  $\text{C}_{10}\text{H}_{13}\text{N}$ , is a colourless liquid (b. p.  $247^\circ$ ) slightly soluble in water. It is distinguished from quinaldine by the blood-red reaction of its salts in aqueous solution with oxidising agents. It reacts with nitrous acid to form a yellow nitroso compound, whence it appears to be a secondary base. The substitution of the basic hydrogen by an alcohol radical, by treatment with the corresponding halogen compound, gives rise to a tertiary base. Of these tertiary bases the author investigated methylhydroquinaldine, a colourless liquid boiling at  $245^\circ$ — $248^\circ$ . Heated with benzotrichloride and zinc chloride it yields a green colouring matter, similar to malachite green. It is noteworthy that quinaldine under similar treatment yields no colouring matter. Quinaldine further unites directly with the alcoholic iodides to form ammonium compounds. Of these the methyl iodide,  $\text{C}_{10}\text{H}_8\text{NCH}_3\text{I}$ , is remarkable for crystallising in extremely long needles (melting point  $195^\circ$ ). Mixed with the corresponding quinoline derivative it yields on treatment with aqueous potassium hydrate a red colouring matter. From the three isomeric toluidines the authors have prepared the corresponding methylquinaldines. The ortho compound is a colourless liquid (boiling point  $252^\circ$ ): it is reduced by treatment with tin and hydrochloric acid to the hydrobase  $\text{CH}_3\cdot\text{C}_{10}\text{H}_{12}\text{N}$ , a colourless liquid boiling at  $261^\circ$ . Paramethylquinaldine crystallises in long colourless prisms, melting at  $60^\circ$ , it boils at  $266^\circ$ . The meta compound melts at  $61^\circ$  and boils at  $264^\circ$ .  $\alpha$ -Quinoline carbonic acid,  $\text{C}_{10}\text{H}_7\text{NO}_2$ , is the product of oxidising quinaldine with chromic acid. G. Schultze (*Berl. Ber.* 1883, 2600) has found that on allowing a mixture of aniline hydrochlorate and aldehyde, in aqueous solution, to stand for some time the hydrochlorate of a new base is obtained, which is readily converted into quinaldine by the action of zinc chloride. A similar compound is formed as the product of the reaction of aldehyde with the free base. These results have an important bearing upon the commercial aspect of the treatment of quinaldine. E. Jacobsen and C. L. Reimer (*Berl. Ber.* 1883, 2602) have prepared a yellow colouring matter,  $\text{C}_{15}\text{H}_{11}\text{NO}_2$ , by the action of phthalic anhydride upon quinaldine. Similar derivatives have been obtained from the homologues of the latter, and from picoline. The general formula of these compounds is  $\text{R}\cdot\text{C}_2\text{O}_2\cdot\text{C}_6\text{H}_4$ . To this class probably belongs the quinophthalone, prepared by Traub (*ibid.* 297) from quinoline obtained from quinquine. Quinoline yellow is regarded by the authors as the prototype of the phthalones. By the action of phthalic anhydride upon paramethylquinaldine, the homologue methylquinophthalone was obtained, crystallising in golden-yellow needles, m.p.  $203^\circ$ . Coal tarpicoline yields two phthalones, probably derive from isomeric picolines. They also dye wool a yellow colour, but are much weaker than the quinoline yellow. In regard to the constitution of the phthalones it is to be observed that they are only formed from the methyl derivatives of pyridine and quinoline, and it is therefore probable that the substitution takes place in the methyl group. On this view the formula of quinoline yellow would be—

W. Spalteholz has also investigated certain colouring matters obtained from coal-tar quinoline. By the action of ethyl iodide this latter is converted into a mixture of ethylquinoliniumammonium iodide, which may be easily isolated in the form of large yellow prisms, and an uncrystallisable body, which on treatment with aqueous potash gives a much larger yield of colouring matter than the pure iodide. This colouring matter is isolated from the resinous product of the reaction in the form of rhombic

plates, having a high beetle-green lustre, which are soluble in alcohol and in acetone to a carmine solution. The same body was obtained by the action of potash upon a mixture of quinoline and quinaldine-ethylammonium iodides. The process consists simply in dissolving 2 parts of the former to 1 part of the latter in hot water, adding potash and heating for a short time, when the colouring matter separates in the crystalline form, and is obtained pure by washing away a resinous body which accompanies it with ether. The composition of the colouring matter is that represented by the empirical formula  $\text{C}_{33}\text{H}_{25}\text{N}_2$ .—C. F. C.

#### Methylene Blue. *Dingl. Polyt. Journ.* 250, 284.

To modify the shade of this colour, which in the pure state is greenish, it is often mixed with methyl-violet or other colouring matter. The admixture is detected by taking advantage of the action of an acid solution of stannous chloride (1 part HCl to 1 part  $\text{SnCl}_2$ ) upon the blue which is to decolorise it completely, whereas the methyl-violet is changed to yellow; so also fuchsin methyl-green and malachite green. On adding sodium acetate the colour is regenerated, and remains unchanged on boiling the solution. The methylene blue, on the other hand, does not reappear.—C. F. C.

#### The Condensation Product of Betanaphthol and Benzaldehyde. W. Trzinsky. *Ber.* 17, 499.

IN a former communication the author made reference to the formation of melinointrisulphonic acid from the product obtained by heating betanaphthol and benzaldehyde with sulphuric acid. This product has been more closely investigated. For its preparation 3 parts of betanaphthol and 1.5 part benzaldehyde were dissolved in 1.5 part alcohol, and treated gradually with 1 part concentrated sulphuric acid. The resulting mass, when recrystallised repeatedly from benzene, chloroform, or carbon disulphide, gave microscopic rhombic plates, melting at  $190^\circ$  to  $191^\circ$  and giving on analysis numbers corresponding with the formula  $\text{C}_{26}\text{H}_{16}\text{O}_3$ . The compound is insoluble in alcohol, ether, and aqueous or alcoholic potash. On heating it with concentrated sulphuric acid it is converted into melinointrisulphonic acid. According to the author's analyses, the condensation of benzaldehyde and betanaphthol is effected in the following manner:—

In the first place, however, the body  $\text{C}_{34}\text{H}_{24}\text{O}_2$  is formed according to the equation—

which is converted into the compound  $\text{C}_{26}\text{H}_{16}\text{O}_3$  by the elimination of one molecule of  $\text{H}_2\text{O}$  from two molecules of the first body.—D. B.

#### Colouring Matters from Pyridine and Quinoline Bases. *Dingl. Polyt. Jour.* 250, 466.

ACCORDING to E. Jacobsen (*D. R. P.* 23, 188, 1882), ( $\alpha$ ) phthalic anhydride yields on heating with the pyridine ( $130^\circ$  to  $230^\circ$ ) and quinoline ( $230^\circ$  to  $310^\circ$ ) bases of coal tar yellow-coloured condensation products. Similar products are in the same way obtained from quinaldine and its homologues—the series of bases prepared by Döbner and v. Miller by the action of paraldehyde upon toluidine, xylidine, naphthylamine, etc., in presence of dehydrating agents. The proportions of the reagents are 1 mol. phthalic anhydride to 2 mols. of base, and 1 mol. lime chloride. A temperature of  $200^\circ$  to  $250^\circ$  is necessary to determine the reaction, which is completed in 5 to 6 hours. The colouring base, being insoluble in water, is easily isolated from the resulting mass. It may be converted into a soluble sulpho compound by solution in sulphonyl chloride. The alkaline salts of this derivative are freely soluble in water, and dye silk and wool without mordant. In place of the phthalic anhydride, nitrophthalic acid or phthalimide may be employed. The derivative obtained from these are similar in colour and properties. (b) Processes are described in the D. P. J.

1883, 247, for the preparation of red colouring matters from the quinoline bases by treatment with benzo trichloride, benzal chloride, benzal bromide, and benzal chlorobromide (Ger. Pat. 23, 967, 1882). These bases differ from the majority of tertiary aromatic amines in yielding these colour bases directly, whereas the latter yield leuco bases. The proportions of the reagents are 1 mol. benzal chloride to 2 mol. of the base, together with zinc chloride. After heating 4 to 5 hours at 150°, the product is treated by distillation with steam, for the removal of the residues of the reagents. The colouring matter is then further purified by crystallisation from alcohol or boiling water, and is lastly converted into a sulphonated derivative by the usual method. (c) A mixture of quinoline and quinaldine, or their homologues reacts with benzotrichloride to form violet red colouring matters, the solutions of which exhibit a yellow-green fluorescence. The probable course of the reaction is that represented by the equation—

The quinoline from coal tar (boiling point 230° to 240°), contains 20 to 25 per cent. quinaldine, and therefore requires only a proportionate addition of the latter base in order that the maximum yield of the colouring matter may be obtained.—C. F. C.

#### New Synthesis of Anthraquinone. W. Panaotovits. Ber. 17, 312.

THE observation made by Fittig, and subsequently by Zinke, that anthraquinone is not an ordinary quinone, but a double ketone, is now generally accepted by the majority of chemists. The author has made a series of experiments on the destructive distillation of ordinary potassium phthalate, and has succeeded in obtaining anthraquinone. The formation takes place according to the following equation:—

This result confirms the theory which represents anthraquinone as a diketone, and also corroborates Pechmann's views on the formation of anthraquinone (Ber. 12, 2125). D.B.

#### Nitroso Phenols. H. Goldschmidt. Berl. Ber. 17, (2) 213.

THE reaction between quinone and hydroxylamine in concentrated solution is so violent as to cause the carbonisation of the product. In dilute solutions, on the other hand, the reaction proceeds smoothly, the chief product being paranitrosophenol (*ibid.* 7, 809), formed according to the equation—

Similarly beta-naphthoquinone and hydroxylamine hydrochlorate react with formation of a body,  $\text{C}_{10}\text{H}_7\text{NO}_2$ , which the author has shown to be beta-nitrosoalphanaphthol.—C. F. C.

#### Probable Number of Homologues and Isomers of Rosaniline. A. Rosenstiehl and M. Gerber. Ber. 17, 139, and Compt. Rend. 98, 433.

SINCE for the formation of rosaniline in the case of the higher homologues of aniline, the hydrogen of the amido group in the para and ortho positions must be replaced by  $\text{CH}_3$ , the authors conclude that, according to theory, thirteen homologues and (with the isomers) altogether eighty different rosanilines are obtainable, if the hydrogen atom of the  $\text{NH}_2$  group in the meta position is also replaced by  $\text{CH}_3$ . Otherwise only nine homologues and altogether thirty rosanilines are possible.—D. B.

#### On the Dyestuff Rocellin. Dingl. Polyt. Jour. 251, 321.

EMIL ROUSSEL communicates various particulars about rocellin in the *Moniteur de la Teinture*, Nov. 1883, p. 271. This colouring matter, which is prepared by diazotising naphthylaminsulfo acid and pairing with beta-naphthol, is known to be one of the purest of the azo series. Although intended chiefly to replace archil (*Rocella tinctoria*), under certain conditions it can be employed to produce red and crimson colours in place of cochineal and alizarin. Hitherto rocellin could not be fixed on vegetable fibres, and it has chiefly been used for dyeing silk. The employment of it for dyeing wool presented many difficulties at first, owing to the extreme avidity with which the wool absorbed the colouring matter, becoming often unevenly dyed unless special precautions were adopted. Roussel's process is as follows: The bath is slightly acidified with hydrochloric acid, heated to 50° and the wool immersed for 15 to 30 minutes. At this point the rocellin is gradually added, and the temperature raised during half an hour to 90°. The wool is finally allowed to remain another half hour in the bath. Under these conditions the goods are uniformly dyed. By the addition of chrysoin a colour is produced which advantageously replaces turkey-red, and is 50 per cent. cheaper. Ink spots can be easily removed from cloth thus dyed, by oxalic acid, the iron salts having no influence on the rocellin, whereas alizarin red is very sensitive to their action. Different shades can be produced by mixing rocellin with indigo carmine, chrysoin, orange, naphthol yellow, etc. The indigo carmine is added towards the end of the operation, with simultaneous addition of sulphuric acid and glauber's salt. These dyes are as fast as cochineal and much more so than archil. The colour of cochineal and archil changes to yellow under the influence of acids, and to violet-red by the action of alkalis, whereas the freshness of colour of rocellin is not affected by either reagent. The cost of production of rocellin dyes is 80 per cent. less than those made with cochineal, and 40 per cent. less than those made with archil. Since the appearance of rocellin the consumption of archil has considerably diminished.—W. M.

\* This formula, reproduced faithfully from the *Berichten*, is utterly wrong, and so leads to wrong results in the equation. Doubtless the expression should be—

ED.

*On the Constitution of the Azonaphthol Colouring Matters.*  
C. Liebermann. Berl. Ber. 10, 2538.

It is generally supposed that the two parallel series of azo compounds, formed by the action of alphanaphthol and betanaphthol respectively on various diazocompounds possess the same constitution, except as regards the position of the hydroxyl group in the naphthol. From an observation communicated to him by Dr. Pfaff, the author was, however, led to an opposite conclusion. Dr. Pfaff finds that when a dilute alkaline solution of alphanaphthol is exactly precipitated with its equivalent of acid, and treated with an aniline salt and sodium nitrite, in the quantities indicated by the equation

the formation of the colouring matter commences at once. If, however, betanaphthol is substituted for the alpha compound the mixture remains almost colourless; but by the addition of a large quantity of alkali a very beautiful colouring matter is produced. The same difference was observed with other bases than aniline. Although many such compounds have been prepared, the different behaviour of alpha- and beta-naphthol has previously escaped observation, because an alkaline solution of the phenol has always been employed. In their properties the colouring matters from alpha- and betanaphthol differ even more widely than in their mode of formation. Thus Dr. Pfaff made the observation that the alpha compound is easily soluble in cold dilute alkali, while the beta compound is only dissolved to a slight extent in a hot concentrated solution of the same, and is precipitated unaltered on cooling. Hence the two substances must be differently constituted. Similar results were obtained by the author with cumidine and betanaphthylamine, and in all these cases the beta compounds were distinguished from the alpha by their greater tendency to crystallisation, their inferior solubility, and generally by their lower melting points. Benzeneazoalphanaphthol

was prepared in a different manner by Typke, though not in a state of purity. The author obtained it, however, in beautiful steel-blue needles by recrystallising two or three times from hot alcohol. The substance melted at 193°, evolving at the same time large quantities of gas, and its solution in concentrated acid possessed a violet-blue colour. Benzeneazobetanaphthol,  $\text{C}_{20}\text{H}_{12}\text{N}_2\text{O}$ , crystallises from boiling alcohol, by rapid cooling in long gold-red, lustrous, leafy crystals, and by slow cooling in long lustrous needles, which possess the colour of cantharidine. It dissolves in concentrated sulphuric acid with a fuchsine-red colour, and it is also soluble in ether, benzene, ligroin, and carbon bisulphide. It melts at about 134°. It is insoluble in an aqueous solution of an alkali, but dissolves readily in sodium alcoholate, being reprecipitated without alteration on addition of water. It possesses weak basic properties, inasmuch as it is dissolved to some extent by concentrated hydrochloric and hydrobromic acids, especially on warming. The hot solution deposits on cooling an unstable green hydrochloride, which gradually gives up hydrochloric acid and becomes red. The alpha compound, on the other hand, is very slightly soluble in these acids. Apparently the alpha compound takes up one molecule, the beta compound two molecules, of hydrochloric acid. The insolubility of the beta compound might be explained by assuming the constitution to be  $\text{C}_6\text{H}_5-\text{N}=\text{N}-\text{OC}_{10}\text{H}_7$ , but this is contradicted by its great stability. Small quantities may even be distilled without decomposition. That the nitrogen is really united with the naphthol radical is also proved by the fact that when the substance is reduced with stannous chloride, aniline and amidobetanaphthol are formed. The identity of the latter product with the alphaamidobetanaphthol obtained from betanaphthol orange was shown conclusively by its conversion into betanaphthoquinone by the method of Stenhouse and Groves. Since the substances required for the preparation of benzeneazobetanaphthol are readily obtained, this body may be most advantageously employed in the production of

betanaphthoquinone. The foregoing observations lead to the conclusion that the beta colouring matter possesses the constitution

It had already been observed in the author's laboratory that such substitution products when in the ortho position readily gave rise to anhydro compounds, and the insolubility of the colouring matter in alkalis, as well as the low melting point, would be explained by assuming the formation of an anhydro compound, thus—

It is very possible that the constitution of the sulphonated azobetanaphthol colouring matters differs similarly from that of the alpha compounds. The difference in their solubility in alkalis would, however, be hidden by the presence of the sulphuryl group. The examination of their salts has been so far neglected, and, moreover, especially as regards basic salts, is attended with some difficulty. The constitution of anthrol

is analogous with that of betanaphthol, and the azo compounds of this substance with diazobenzene and diazocumidine are similarly insoluble in cold alkalis. The difficulty with which the formation of the betanaphtholazo compounds is attended is explained by the fact that the diazo group cannot take the para position in the betanaphthol molecule, but is obliged to take the ortho position. The diazo group thus behaves like other acid radicals, and the general belief that it always occupies the para position is incorrect. A further proof of this fact is afforded by the disazo compounds. Even when the para position is unoccupied the presence of substitution groups in the molecule may cause the diazo groups to take some other position. The separation of isomeric phenol substances may sometimes be effected by precipitating them one after the other as azo compounds by adding different diazo substances to the mixture.

S. Y.

*Orthoamidazo Compounds.* E. Nötting and O. N. Witt.  
Berl. Ber. 17, 77.

It has hitherto been assumed that by the action of diazo compounds on amines and phenols, amido or oxyazo compounds can only be formed when the para position is vacant—that is to say, the azo group does not attach itself near a side chain. The authors show, however, in this paper that it is possible to obtain compounds where the two groups are attached to neighbouring atoms, i.e., orthoamidazo compounds. Previous attempts by various chemists to prepare an amidoazo body from paratoluidine have failed, diazoamido compounds only having been obtained, whilst it has been stated that orthotoluidine gives an amidoazotoluene without even the intermediate formation of a diazoamido compound. The authors have found that this latter statement is only true if ordinary orthotoluidine be used, but that if the absolutely pure substance be employed an easily crystallisable intermediate diazoamido compound is obtained. They further find that the failure to obtain an amidoazo compound from paratoluidine is to be ascribed to the use of alcohol as a solvent, and that if, instead, paratoluidine be

employed, the substance can be obtained without difficulty. Diazoamidoparatoluene prepared in the ordinary manner was added from five to six times the quantity of paratoluidine previously melted on a water-bath. One molecule of paratoluidine hydrochloride for each molecule of the diazoamido compound was then added, and the mixture warmed on the water-bath to 65° for ten to twelve hours. The hydrochloric acid is then exactly neutralised with caustic soda, the salt solution removed, and the excess of toluidine removed by steam. The residue is the new amidoazotoluene, which can be purified by crystallisation from alcohol. It forms brilliant orange-red needles, easily soluble in hot alcohol, acetic ether, benzene, etc., and melting at 118.5. Analysis confirmed the formula,  $C_{14}H_{15}N_3$ . Amidoazoparatoluene differs from all other hitherto described amidoazo bodies in giving salts which when solid are pale yellow but in solution are green. The slightest admixture, especially of any other ordinary amidoazo compound, giving red salts, destroys the green colour on treating the alcoholic solution with hydrochloric acid. Apart from this, the new substance, behaves quite like other amidoazo compounds. The hydrochloride crystallises in yellowish-white needles. The authors have prepared the acetyl and benzoyl derivatives, and the sulphonic acid by treatment with fuming sulphuric acid. The disulphonic acid is a yellow colouring matter with a slightly redder tint than the yellow mixture of the sulphonic acids of amidoazobenzene found in commerce. Diazo compounds obtained by the action of nitrous acid on amidoazoparatoluene or its sulphonic acids give red colouring matters with  $\alpha$ -naphthol or its sulphonic acids. By the action of reducing agents the new amidoazo body gives paratoluidine and orthotoluylenediamine, the first example of an amidoazo compound of the benzene series giving by reduction an orthodiamine. It has not been found possible to obtain a quinone or saffranin from the products of reduction, which therefore cannot contain a paradiamine, and in which no metadiamines have been detected. The characteristic ethenyl base of orthotoluylenediamine, on the other hand, can be prepared by means of acetic anhydride. From these facts it follows that the constitution of the new amidoazotoluene is—

The authors have obtained similar compounds from other para-amido bodies, e.g., paratolylamine. With the salts of primary bases amidoazotoluene gives colouring matters of the indulin series, in the study of which the authors are engaged. In connection with the above research a French patent was taken out on May 9, 1882. A German patent has in all instances been refused.—A. S.

#### Synthesis of Anthraquinoline. C. Graebe. Ber. 17, 170.

SKRAUP having shown that, by the action of nitrobenzene, glycerol, and sulphuric acid on betanaphthylamine, betanaphthoquinoline is formed, it was thought that on treating anthramine in a similar manner anthraquinoline might be produced. The object of this experiment was to determine whether the body which the author obtained on heating alizarin blue with zinc dust is produced in this case. From his former investigations the author concluded that the constitution of anthraquinoline from alizarin blue is expressed by the following formula:—

Since the amide in anthramine occupies the same position as the nitrogen atom in alizarin blue the possibility

was given that anthramine would yield the same anthraquinoline. On investigation this was found to be the case. On heating anthramine with nitrobenzene, glycerine, and sulphuric acid anthraquinoline melting at 170° was produced. It forms yellow salts, the solutions of which are highly fluorescent.—D. B.

#### On the Violet Derivatives of Triphenylmethane. O. Fischer and G. Körner, Berl. Ber. 16, 2904.

It was stated some months ago by O. Fischer and L. German (*Ber. Ber.* 16, 706) that the reduction product of methyl-violet, which melted at 173°, contained no hydrogen in an amido group capable of substitution, and that it was therefore, in all probability, hexamethyl paraleucaniline. It was also shown that the tetramethylparaleucaniline obtained from paranitrobenzaldehyde and dimethylaniline yield an acetyl compound, which on oxidation gives rise to a green colouring matter. Further investigation has shown that besides the reduction product, which melts at 173°, methyl-violet yields other products, from which acetyl compounds may be prepared. Thus on crystallising the reduction products from alcohol the hexamethyl compound separates first, and the mother-liquor is then found to contain other compounds, which behave like tetramethylparaleucaniline when treated with acetic anhydride, and consequently with oxidising agents. Meanwhile the authors received from Dr. Koch a specimen of a green colouring matter which he had prepared from methyl-violet by treatment with acetic acid, and which proved to be a homologue of the acetyl green described above, for by removal of the acetyl group a violet was obtained which differed from the tetra- and from the hexa- methyl-violet, and was probably the pentamethyl compound. The action of acetic anhydride shows at once whether free hydrogen is still present in the amido group. A small quantity of methyl-violet is warmed with acetic anhydride and sodium acetate, and a drop of the dilute aqueous solution placed on filter paper. The formation of a green rim round the violet stain proves that the violet contains lower homologues of hexamethyl-violet. The violet investigated by the authors was prepared from pure dimethylaniline. It was heated for several hours on the water-bath with acetic anhydride and fused sodium acetate, dissolved in water, and colouring matters precipitated with sodium chloride and zinc chloride. The substance which was thus freed from acetic acid was dissolved in water and fractionated by precipitation with sodium chloride. The unaltered violet came down first, and on reduction yielded hexamethyl paraleucaniline. The green mother-liquor was treated with alkali, and the resulting gray flakey precipitate was filtered, dried, and boiled with absolute alcohol. The alcoholic solution yielded crystals, which after purification melted at 223° to 225°. The mother-liquor contained other products which were not investigated. The analysis of the acetyl compound gave numbers corresponding to the formula  $C_{28}H_{33}N_3O_3$ , or diacetylpentamethylpararosaniline. On investigation it was found that one acetyl group was combined with nitrogen, the other with the oxygen of a carbinol group. The alcoholic solution when exposed to the air assumed a violet colour, and when warmed with acetic acid yielded the green colouring matter. Unfortunately this substance, though very beautiful, is unstable, and is therefore not of technical value. *Acetylpentamethylparaleucaniline* is obtained by reduction of the solution of the green acetyl compound in acetic acid by means of zinc dust, and precipitation with an alkali. It is obtained in colourless needles by recrystallisation from alcohol, which melt at 143° to 144°. Its composition was confirmed by analysis. *Pentamethylparaleucaniline*: By removal of the acetyl group from the compound last described by boiling with concentrated hydrochloric acid, a product is obtained which crystallises from alcohol in colourless needles. The crystals obtained from its solution in benzene melted at 115° to 116°, and were found to possess the composition  $C_{24}H_{29}N_3$ . The colour of the compound formed by oxidation of this body lies between that of the tetra- and of the hexa- methyl-violet. That the substance is pentamethylparaleucaniline

is proved by the fact that it takes up only one acetyl group, and that the acetyl compound differs from acetyl-tetramethylparaleucaniline. The position of the amido groups is the same as in the tetra- and hexa-methyl compounds and in paraleucaniline, because they all yield the same product when treated with methyl-iodide and methyl-alcohol. The analysis alone of the compound would not be sufficient to prove whether the substance contained four or five methyl groups, but the fact that only one acetyl group is taken up decides the question. The explanation of the formation of methyl-violet, proposed by E. and O. Fischer (*Ann. Chem. Pharm.* 194, 295), is in accordance with the results described, but the explanation may now be simplified. It was shown that formaldehyde is produced by the oxidation of dimethylaniline, and it was assumed that the formaldehyde or formic acid united with three molecules of dimethylaniline to form hexamethylparaleucaniline, and that by further oxidation one methyl group was removed, and the pentamethyl compound produced. It is now known, however, that at least two homologous violets are formed by the oxidation of dimethylaniline. The authors now assume that the oxidised methyl groups from the dimethylaniline unite not only with three molecules of dimethylaniline to form the hexamethyl compound, but with two molecules of dimethylaniline, and the molecule of monomethylaniline produced by the reaction, to form pentamethylleucaniline. So also a combination of methane with one molecule of dimethylaniline and two of monomethylaniline would give the tetramethyl compound. The process of formation of methyl-violet is thus analogous with that of Hofmann's fuchsin, and also with that of diphenylamine blue. The great care taken by manufacturers to obtain pure dimethylaniline appears from the above reasoning to be unnecessary. In order to make the process perfect some substance should be employed which would liberate the methane carbon atom, as in Hofmann's fuchsin process. Probably the addition of a benzyl group would then be unnecessary, on account of the pure blue colour of the hexamethyl compound, and because it is only the lower homologues which are acted on by chlorobenzyl. Thus O. Fischer and L. Germann have shown that an alcoholic solution of the leuco base of hexamethyl-violet is not acted on by chlorobenzyl in presence of an alkali, while the authors find that the unaltered hexamethyl-violet is contained in benzyl-violet. *Methyl-Green*: The authors find that by removal of methyl-chloride the hexamethyl-violet is formed, and the same substance was obtained from crystal green (the zinc chloride double salt), the mother-liquor containing only traces of other leuco violets. It thus appears that methyl-green is a pure substance, and the facility with which it may be crystallised is thus explained. While it is extremely difficult to crystallise commercial methyl-violet, the zinc double salts both of penta- and hexa-methyl-violet are readily obtained in beautiful needles or prisms.—S. Y.

*Resorcin Blue.* Justus Andeer. *Centrabl. Med. Wissenschaft.* 1883, 47.

By heating with egg albumen or with urea (two molecules to one) resorcinol gives a blue sublimate.—A. S.

*Colouring Matters Obtained by the Simultaneous Oxidation of Monamines and Paradiamines.* R. Nietzki. *Berl. Ber.* 17, (2), 223, 227.

The author has investigated the action of ferric chloride upon an acid solution of tetramethyldiamidodiphenylamine and in presence of hydrogen sulphide. The first stage in the reaction is the formation of the green colouring matter  $C_{16}H_{20}N_4Cl$ . This latter then undergoes decomposition, probably according to the equation:—

and the resulting dimethylparaphenylenediamine is converted by the action of the hydrogen sulphide into methylene blue. The author obtained only 5 per cent. of the theoretical yield of the colouring matters, a fact which confirms the view of its being formed indirectly.

The oxidation of paradiamines in presence of primary, secondary, and tertiary bases, is the source of a large number of new colouring matters. Aniline black is probably a member of this series of products. By oxidising paraphenylenediamine in presence of diphenylamine the author obtained a body similar to that which constitutes the green stage of the above. The same substance is also produced, together with quinone, by the oxidation of paramonamidodiphenylamine. Its composition is represented by the empirical formula  $C_{18}H_{12}N_4$ . The close relationship of paradiamidodiphenylamine to the safranines leads to a few observations in conclusion upon this group of compounds. In regard to the empirical formula of phenosafranin the author allows the correctness of that established by Bindschedler (*ibid.*, 16, 564), viz.,  $C_{18}H_{12}N_4$ . At the same time he considers this author in error in assigning 4 atoms of H as necessary for its reduction to the leuco base, 2 atoms H only being required. The error is probably caused in the use of ferrous sulphate, the results obtained with stannous chloride being more trustworthy. The author is engaged in the investigation of the constitution of phenosafranin.—C. F. C.

*On 1, 2, 4 Orthoxyldine.* O. Jacobsen. *Ber.* 17, 159.

SOME time ago Wroblewsky described a new xylydine, which he regarded as orthoxyldine [1, 2, 4], without, however, explaining its formation. This substance when treated with nitrous acid yielded a nitroso compound identical with that which the author had previously obtained by the nitration of orthoxylylene. The author has recently prepared chemically pure orthoxylylene on a large scale from coal-tar oils, and having had large quantities of this substance at his disposal, has made an investigation in order to determine whether orthoxyldine [1, 2, 4] described by Wroblewsky is a derivative of orthoxylylene. He found that this substance is not orthoxyldine, nor is its essential constituent this body. Nitro-orthoxylylene,  $C_6H_3.Me_2.NO_2$  [1, 2, 4], is prepared by introducing pure orthoxylylene into eight to ten times the quantity of cold fuming nitric acid. It crystallises from alcohol in long vitreous light yellow prisms, sparingly soluble in cold alcohol. Melting point 29°, boiling point 258°, specific gravity at 30° 1.139. Orthoxyldine,  $C_6H_3.Me_2.NH_2$ , has been prepared from nitro-orthoxylylene by means of acetic acid and iron and tin and hydrochloric acid. It melts at 49° and boils at 226° sp. gr. at 17.5° 1.0755. It is sparingly soluble in cold water, readily soluble in hot water, alcohol, and ether. It crystallises in transparent vitreous rhombic plates, or when cooled gradually in large well-defined crystals belonging to the monoclinic system. Its aqueous solution is not coloured by a solution of chloride of lime. The solutions of its salts impart to firwood a yellow colour. The hydrochloride,  $C_6H_3.Me_2.NH_2.HCl + H_2O$ , forms long, thin prisms, readily soluble in water. Acetoxylide,  $C_6H_3.Me_2.NHAc$ , obtained by the action of acetic anhydride or acetic chloride on orthoxyldine, crystallises from alcoholic solutions in long vitreous prisms, melting at 99°. It is readily soluble in alcohol and hot water. In order to determine the constitution of orthoxyldine the author converted it into the corresponding xylenol, which was found to be identical with the 1, 2, 4, orthoxylenol obtained from orthoxylylene sulphonic acid. Its boiling point was 225°, and it melted at 62.5°.—D. B.

*The Action of Aldehydes on Phenols.* A. Michael and A. M. Comey. *Amer. Chem. Journ.* 5, 349-353.

THIS paper is concerned with the action of aldehydes of the fatty series on phenols. When a solution of equal parts of aldehyde and orein in 8 parts of alcohol is heated for one minute at 100° with three drops of hydrochloric acid, a bright yellow substance of the formula  $C_{18}H_{20}O_4$  separates out in small round plates, which darken in the air at 100°, are insoluble in the ordinary solvents, and readily oxidise in alkaline solution. Resorcin, in place of orein, gives likewise, under similar conditions, a compound which, however, decomposes at 100° in a stream of carbon dioxide. When a mixture of

5 parts of chloral hydrate, 10 parts of resorcin, and 40 of water are heated for 12 to 24 hours with reversed condenser, a bright yellow substance separates out, partly before and partly after cooling, which possesses the formula  $C_8H_6O_3$ —

This substance melts with decomposition at a high temperature, is somewhat easily soluble in hot water, extremely so in hot alcohol and acetic acid. It is probably white when pure, but turns yellow at once in the air, crystallises from alcohol in yellow needles, and gives with alkalis a solution which darkens on exposure to the air, whilst by heating with acetic anhydride and sodium acetate it gives the compound  $C_8H_4O_3.(C_2H_5O)_2$ . This separates from alcohol in prisms which melt at  $159^\circ$ , are soluble in hot water, slightly soluble in cold, and moderately so in hot alcohol. The benzoyl compound,  $C_8H_4O_3.(C_6H_5O)_2$ , which is produced by the action of benzoyl chloride on the substance  $C_8H_6O_3$  at  $120^\circ$ , forms faintly reddish needles, melting at  $165^\circ$ , and possessing similar solubility to the acetyl compound. With orcin chloral hydrate gives a substance melting at  $250^\circ$ , whilst its acetyl derivative melts at  $190^\circ$ —A. S.

*Violet Derivatives of Triphenyl Methane.* O. Fischer and G. Koerner. Berl. Ber. 17, 98.

IN this paper the authors describe a new synthesis of hexamethylparaleucaniline by the action of orthoformic ethers or dimethylaniline. If 1 part of orthoformic ether and 3 to 4 parts dimethylaniline be heated for some hours on a water-bath, with the addition of 2 parts of zinc chloride, the following reaction takes place:—

The substance is isolated by freeing the blue-coloured mass resulting from the above operation from excess of dimethylaniline by a current of steam, dissolving in hydrochloric acid, and pouring into cooled ammonia. It separates out in crystals, which, after one crystallisation, appear as beautiful shining plates, which melt at  $172^\circ$  to  $173^\circ$ . Nearly the theoretical yield is obtained.—A. S.

*Preparation of Orthonitrobenzaldehyde.* A. Ehorn. Berl. Ber. 17, 119.

AFTER reviewing the processes previously described for the preparation of this substance, the author recommends the following method, based on the fact that the alkali salts of orthonitrocinnamic acid, when carefully treated with potassium permanganate, give the aldehyde, which, as soon as formed, is absorbed by benzene. 50grms. commercial orthonitrocinnamic acid, suspended in  $2\frac{1}{2}$  litres of water, are neutralised with a solution of sodium carbonate, and filtered into a large stoppered bottle, containing 1 litre of benzene. The fluid is kept constantly cool by the addition of ice, and 1,225c.c. of a cold saturated (6 per cent.) solution of potassium permanganate added in small portions at a time, with thorough shaking after each addition. The manganese dioxide which separates is best got rid of by the addition of a warm solution of 155grms. sodium sulphite and sufficient hydrochloric acid to generate the quantity of sulphur dioxide required to dissolve the manganese dioxide, the liquid being kept in motion by a current of air. The fluid now consists of two layers, between which is generally a solid substance consisting of unattacked orthonitrocinnamic acid and orthonitrobenzoic acid. The watery layer may be siphoned off, and the benzene layer filtered and distilled, upon which the orthonitrobenzaldehyde remains as a brown-coloured liquid, which solidifies to a crystalline mass on cooling, and can be dried on an unglazed porcelain plate. The method gives usually from 50 to 53 per cent. of the theoretical yield, which, however, can be increased by using more dilute solutions and adding plenty of ice. It is not proposed to utilise the process commercially, owing to its costliness.—A. S.

*On the Constitution of Methylene Blue.* E. Erlenmeyer. Berl. Ber. 16, 2857. *On Methylene Blue and Allied Colouring Matters.* August Bernthsen. Berl. Ber. 16, 2896.

VARIOUS views are held by different observers as to the constitution of methylene blue and violet and the corresponding leuco compounds. Thus Möhlau places the sulphur atom between two nitrogen atoms; Erlenmeyer between a nitrogen atom and a carbon atom of one of the benzene rings; while Bernthsen considers that it is united to a carbon atom of each benzene molecule. Erlenmeyer finds that methylene blue may be prepared from Bindschedler's green by treatment with sulphuretted hydrogen and ferric chloride. In opposition to Nietzki he considers that Bindschedler's green is constituted thus:—

and writes the formula of the compound obtained by the action of sulphuretted hydrogen as below:—

or more probably

Hence the constitution of methylene blue and white would be respectively—

and

Bernthsen attempts\* to solve the problem by preparing the compound from which the different colouring matters are derived. This compound the author believes to be thioldiphenylamine, to which he gives the constitution

Pointing out the analogy between methylene blue and Lauth's violet, the author suggests that the composition of these substances may be best represented by the formulae  $C_{16}H_{17}N_3S$  and  $C_{12}H_9N_3S$  (or possibly  $C_{12}H_{11}N_3S$ ) in place of those generally adopted, viz.,  $C_{16}H_{19}N_3S$  and  $C_{12}H_{11}N_3S_2$  ( $=C_{12}H_{10}N_3S$ ). According to the author these colouring matters are derived from thioldiphenylamine, the leuco violet being a diamidothioldiphenylamine, and the leuco blue a tetramethyldiamidothioldiphenylamine. The research is not yet completed, but the following results are given in support of the author's view. Thioldiphenylamine,  $C_{12}H_9N_3S$ : Diphenylamine and sulphur are heated together to between  $250^\circ$  and  $300^\circ$  until the evolution of sulphuretted hydrogen has ceased. The product is then distilled and purified by repeated crystallisation from its hot alcoholic solution. The above formula was confirmed by analysis, and the reaction may be expressed thus—

Thioldiphenylamine is deposited from alcohol in the form of light yellow, glittering, leafy crystals. It is also more soluble in hot than in cold glacial acetic acid and benzene, and may be crystallised from these solvents. The sub-

\* The first formula is obviously incorrect, since it would make sulphur a triad and carbon a heptad element.—S. Y.

stance is not a base. It melts at  $180^{\circ}$  (uncorrected), and distils with but little decomposition at about  $371^{\circ}$ . The vapour density, 196.4, confirms the formula  $C_{12}H_9NS$ . Thiodiphenylamine absorbs oxygen from the air, and the surface of the crystals assumes a green colour. Its alcoholic solution, when exposed to the air, becomes at first deep green and finally red, while the addition of ferric chloride produces a green precipitate. Nitrous acid or the fumes of nitric acid colour the solid a deep brown-red. The solution of thiodiphenylamine in cold concentrated sulphuric acid possesses a greenish-brown colour, but in thin layers it appears rose-red. The addition of water produces a crystalline precipitate. Minute quantities of thiodiphenylamine may be detected by means of the following colour reactions. A little glacial acetic acid is first added to the substance, and then a few drops of fuming nitric acid, when a red solution is obtained, which, on addition of water, deposits a yellow nitro compound. On boiling this with an acid solution of stannous chloride a colourless solution is formed, which, after removal of the tin by means of zinc, gives, with excess of ammonia, an intense violet coloration. The addition of ferric chloride to the reduced solution gives rise to a reddish-violet precipitate or a violet coloration. Acetothiodiphenylamine,  $C_{12}H_9NS(C_2H_3O)$ , is prepared by heating the substance for some hours with excess of acetic anhydride. The yield is quantitative. The acetyl derivative crystallises well, and its colour reactions are similar to those of thiodiphenylamine, methylthiodiphenylamine,  $C_{12}H_9NS(CH_3)$ , and ethylthiodiphenylamine,  $C_{12}H_9NS(C_2H_5)$  are formed by the action at  $100^{\circ}$  to  $110^{\circ}$  of methyl alcohol and iodide and ethyl alcohol and bromide respectively on thiodiphenylamine. They both crystallise remarkably well. The methyl derivative melts at  $99.3^{\circ}$ , the ethyl at  $102^{\circ}$ . Thus thiodiphenylamine possesses a hydrogen atom which is easily replaced by alcoholic and acid radicals. That this hydrogen atom is not combined with the sulphur is shown by the chemical properties of thiodiphenylamine, which differ entirely from those of a mercaptan. Hence the hydrogen atom must be combined with nitrogen, and the sulphur must have taken the place of two hydrogen atoms in the benzene rings. The constitution of the compound is therefore most probably—

The oxidation products of the compound were then studied, the methyl derivative being employed, to avoid the presence of the amido group. The oxidation was effected in a boiling aqueous solution of methyl thiodiphenylamine by means of potassium permanganate, and a product was obtained which crystallised from hot alcohol in colourless or reddish crystals, which melted at  $222^{\circ}$ . The composition of the substance was found by analysis to be  $C_{13}H_{11}NSO_2$ . The yield was remarkably good. The substance possesses neither basic nor acid properties, and is unaltered by boiling concentrated alkalis and acids, nor does it give the colour reactions described above. The oxidation product is most probably methyl diphenylaminesulphone, and the constitution of the compounds described is probably as follows—

Methylthiodiphenylamine. Methylthiodiphenylaminesulphone. The relationship of thiophenylamine to Lauth's violet and methylene blue is shown by the following observations: The nitration of thiophenylamine with fuming nitric acid takes place easily, and with considerable evolution of heat. The product which crystallises in minute needles dissolves in alkalis with a blood-red colour. By reduction with stannous chloride the colourless tin double salt of the leuco base is formed. Weak oxidising agents convert this compound into a violet colouring matter, which bears a strong resemblance to Lauth's violet, but their identity is not yet determined. When dimethylphenylene green,  $C_{16}H_{19}N_3$ , is reduced

with sulphuretted hydrogen, tetramethyldiamidodiphenylamine is formed, and when the latter compound is saturated with the gas, and then oxidised with ferric chloride, methylene blue is found among the products of the reaction.—S. Y.

*On the Condensation of Aromatic Aldehydes with Phenols.*  
T. Trzeinski. Berl. Ber. 16, 2835.

It has been shown by the researches of Baeyer and his pupils that one molecule of the fatty aldehydes (methylal, ethylaldehyde, and chloral) and two molecules of the aromatic aldehydes (benzaldehyde and salicylaldehyde) combine respectively with two molecules of a phenol, one molecule of water being liberated. Baeyer explains the reaction by assuming that an intermediate compound is formed thus—

and that two molecules of this compound combine, with liberation of one molecule of water. The more recent researches of Liebermann on the compounds formed by the union of salicylaldehyde and paraoxybenzaldehyde with phenol led to no precise demonstration of the manner in which condensation takes place. The composition of the product obtained from salicylaldehyde did not agree with the formula required by either of the equations—

and Liebermann considered that the colouring matter obtained from paraoxybenzaldehyde and phenol was formed according to the equation—

and that it possessed the constitution—

dioxibenzhydrol,  $CH(OH).(C_6H_4.OH)_2$  being first formed and then oxidised by the sulphuric acid. Though the analytical numbers obtained by Liebermann do not agree well with his hypothesis, yet they show that in this case the reaction described by Baeyer does not take place. The investigation of the subject was undertaken by the author, who found that when betanaphthol instead of phenol is warmed with paraoxybenzaldehyde and concentrated sulphuric acid on the water-bath, a very stable orange-yellow crystalline substance is formed, which is the trisulphonic acid of a condensation product, of the composition  $C_{34}H_{24}O_9$ . The compound is best prepared by mixing 5 parts of the aldehyde with 12 parts of betanaphthol, and adding 50 parts of concentrated sulphuric acid. The liquid becomes slightly warm, and the colour becomes at first a deep violet and then red. The mixture is warmed for  $2\frac{1}{2}$  to 3 hours on the water-bath, during which time a slight evolution of sulphur dioxide occurs. The crude product is precipitated by addition of water, filtered, and converted into the easily soluble calcium salt by boiling with calcium carbonate. After repeated crystallisation from hot water the salt is treated with dilute hydrochloric acid, whereby a deep yellow compound of the new substance with hydrochloric acid is formed. By heating in the air-bath to  $120$ – $130^{\circ}$  the hydrochloric acid is removed and the pure substance, to which the author gives the name melinointrisulphonic acid, is obtained. When pure the acid is insoluble in absolute alcohol but moderately soluble in water. In thin layers it possesses a beautiful rose-red colour with a green fluorescence, in larger masses the colour is pure yellow. It is not attacked by boiling nitric acid, and its solutions in this acid and in concentrated sulphuric acid exhibit a beautiful green fluorescence. It is precipitated from its aqueous solution by mineral acids in the form of yellow flakes. An alkaline solution of the acid is reduced by zinc dust, but the compound formed has not been analysed. It is easily oxidised to melinointrisulphonic acid. The acid does not melt at  $300^{\circ}$ , and is stable at that temperature. It is a strong acid, and is not liberated from its salts by dilute acetic acid. It was found on analysis to possess the composition  $C_{34}H_{17}O_9(SO_3H)_3$ . A number of salts were prepared and analysed by the

author. Their composition is represented by the general formula  $C_{34}H_{17}O_5(SO_3Me)_3$ . The yield from 5grms. paroxybenzaldehyde and 12grms. naphthol was usually 2grms. melinointrisulphonic acid. Schäffer's betanaphtholsulphonic acid may be substituted for the naphthol; but the acid is not formed by the action of salicylaldehyde on betanaphthol, or of parabenaldehyde on alphanaphthol or on betanaphthol. It may, however, be prepared, and more economically than by the method described, by heating benzaldehyde and betanaphthol with concentrated sulphuric acid to 200° or 220°. According to Baeyer, when a hot alcoholic solution of benzaldehyde and naphthol is treated with a mineral acid the following reaction occurs:—

When, however, equivalent quantities of the two acids are heated to 200° to 220° with concentrated sulphuric acid, sulphur dioxide is evolved and melinointrisulphonic acid is formed. In practice it is more convenient to prepare Baeyer's condensation product, and to heat this with the concentrated acid. A solution of 1 part of benzaldehyde and 2 parts of betanaphthol in 1 part of alcohol is treated with 0.6 part concentrated sulphuric acid, and the mixture constantly stirred. The product is filtered, washed with alcohol, and dried at 100°. To one part of this substance 4 parts of concentrated sulphuric acid, heated to 100°, are gradually added. The solution is then heated to 200° in a porcelain basin, when sulphur dioxide is copiously evolved. The acid is then precipitated with water. The formation of the acid may be represented thus—

It would appear that at first oxyphenyloxy-naphthyl-carbinol

is formed, and that a condensation of two molecules of this substance then occurs, water being liberated. This compound

is then oxidised by the sulphuric acid, and the body

is thus formed. The separation of the other two molecules of water might be effected either by the union of two hydroxyl groups with two hydrogen atoms of the benzene or naphthalene groups or with the hydrogen atoms of two other hydroxyl radicals. In the latter case the structural formula of the compound would be either

The composition of melinoin shows that the condensation does not take place in the manner described by Baeyer, for three molecules of water are removed, and also two hydrogen atoms are oxidised to water. A similar oxidation was noticed by the author in the formation of a colouring matter from salicylaldehyde and phenol. The formation of aurin and its homologues by heating phenols with formic acid and zinc chloride (Nencki, *Journ. für prakt. Chemie.* 25, 273) may be represented thus—

and it might be expected that the same or an isomeric

compound would be formed by the action of salicylaldehyde or benzaldehyde on phenol, thus—

Liebermann prepared a colouring matter by acting on phenol with salicylaldehyde, but found that it differed entirely both from aurin and from rosolic acid. The same compound was prepared by the author, who found its composition to be  $C_{19}H_{11}O_4$ . Since it contains one more oxygen atom than aurin, the author names it oxyaurin, and represents its formation by the equation

S. Y.

*The Action of Aldehydes on Phenols.* Arthur Michael. *Amer. Chem. Journ.*, 5, 338—349.

MIXTURES of aromatic aldehydes with phenols are converted into white resins by the action of quite small quantities of acids, the rate of conversion depending upon the acid used. Thus 20grms. of benzaldehyde and resorcin are converted into resin by one drop of acid. In order to prepare the resin pure, one drop of hydrochloric acid is added to a solution of equal parts by weight of benzaldehyde and resorcin in three parts of alcohol, the mixture filtered when cold, and the filtrate poured into water. The precipitate is washed with water, dissolved in alcohol, again precipitated by water, and dried at 100° in a stream of carbon dioxide or hydrogen. In this way a slightly reddish powder is obtained, which melts with decomposition at 330°, and possesses the composition  $C_{26}H_{20}O_4$ . The undried resin is white, melts under boiling water, dissolves very readily in alcohol, ether, glacial acetic acid, and benzene, and changes rapidly on heating into a dark-brown substance. The colourless solution in alkalis also soon becomes dark brown. The resin dried in a vacuum possesses the composition  $C_{26}H_{20}O_4.3H_2O$ . An amorphous compoundless soluble in alcohol and benzene, and possessing the composition  $C_{26}H_{20}O_4.(C_2H_3O)_4$  is obtained from the white resin by boiling with acetic anhydride and sodium acetate. The resorcinbenzaldehyde resin is converted by the further action of dilute acids into two crystalline products, of which one dried at 100° is isomeric with the resin dried at 100°, but when dried in the air contains  $4H_2O$ . In order to prepare this, a hot solution of 4 parts of benzaldehyde, 10 parts of resorcin, and 20 parts of water is mixed with 3c.c. to 4c.c. of water containing a few drops of hydrochloric acid, heated on the water-bath as long as a precipitate forms, then filtered, treated with acid, and again heated till a precipitate is formed. From this, boiling alcohol extracts, the substance  $C_{26}H_{20}O_4.4H_2O$ , crystallising in quadratic tables or prisms, while the second remains behind in small quantity. The first is moderately soluble in hot alcohol, scarcely soluble in cold alcohol, and insoluble in water and ether. It gives with alkalis a solution rapidly darkening in the air. When boiled with sodium acetate and acetic anhydride it is converted into  $C_{26}H_{16}O_4(C_2H_3O)_4$ , the substance which crystallises from xylene, and is insoluble in alkalis, giving in alkaline solution, by means of sodium amalgam, apparently a reduction product,  $C_{26}H_{22}O_4$ , resembling in its properties the so-called crystallisable resins. Phosphoric acid, and still more organic acids (acetic, formic, and oxalic), cause a slower formation of resin than hydrochloric and sulphuric acids. Experiments with other aromatic aldehydes and phenols showed that the facility with which the formation of resin is caused by small quantities of acids depends upon the nature of both compounds. The formula—

is given provisionally to the benzaldehyderesorcin resin. Fixed alkalis and potassium carbonate likewise produce a resin in a mixture of benzaldehyde and resorcin. The author considers it probable that certain vegetable resins arise from aldehydes and phenols which come in contact with the cell contents.—A. S.

## VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

*Action of Hypochlorites and Chlorates in Dyeing.*  
Dingl. 251, 336.

J. PERSOZ, of Paris, gives a few particulars in the *Bulletin de la Société Chimique de Paris*, 1884, p. 620, which may serve as an amplification of H. Schmid's paper on Witz's oxidation of cellulose (*Dingl. Jour.* 1883, 250, 271). In order to mordant woven goods composed of different fibres with oxide of iron, some dyers use baths of nitro-sulphate of iron and a warm solution of chloride of lime. The object of the latter cannot be to oxidise the iron salt, as it is already in the state of sesquioxide. It acts partly as precipitant of the hydrate of iron and partly in the manner described by Witz, the chlorine or hypochlorous acid increasing the absorptive power of the fibres in the presence of metallic oxide mordants. The oxide of iron is more completely fixed in this case than when precipitated by an alkali or alkaline carbonate. J. Persoz, sen., proposed a similar process for mordanting with oxide of iron mixtures of vegetable and animal fibres which have not the same affinity for metallic oxides. Equivalent quantities of chlorate of potassium and sulphate of iron are dissolved in the cold, the two solutions mixed together, and the woven material is introduced into the dilute bath, which is gradually heated. The chlorate of iron, produced in the first instance by double decomposition, splits up, precipitating hydrate of iron in the fibre. This mordanting is also favoured by the chlorine oxidation products, which are set free and act on the fibres in a well-known manner. If a piece of woven material composed of silk, wool, dog-hair, cotton, flax, etc., be mordanted in this manner, and afterwards dyed with logwood, the colour will be perfectly uniform. J. Persoz, jun., found that this process for mordanting could not only be applied to textile fibres, but also to other carbohydrates, and proposes the following process for mordanting, for example, potato or grain starch, with oxide of iron and dyeing with Berlin blue. Five parts chlorate of potassium and seven parts sulphate of iron are dissolved separately in cold or lukewarm water. Fifteen parts potato starch are ground with water, and the different solutions mixed together in a vessel and diluted to 400 parts. These proportions give a medium blue. The mixture is slowly heated to 55° with constant stirring. When the starch appears sufficiently coloured it is allowed to cool and settle, and is washed by decantation. The mordanted starch is dyed in a very dilute bath of yellow prussiate of potash, which contains one part of concentrated oil of vitriol to two parts of the latter salt, and is slightly warmed. When the saturation is completed the starch is again washed by decantation. A microscopical examination shows that the starch is uniformly dyed, and has preserved its characteristic structure unaltered. Grain starch exhibits the same properties, but less markedly. It is probable that the salts of alumina, chromium, etc., would behave similarly under given conditions, and thus one would be able to dye mordanted potato starch with logwood, alizarin, and astringent dyestuffs, in different shades. The author says that it was the custom to add a certain amount of chlorate of potassium to the ordinary mordant, which aided its fixation in the fibre. But this has been discontinued, as the mixture did not keep well, and gave rise to premature deposition of insoluble metallic oxide in the dye.—W. M.

*On the Mineral Colours Employed in Calico Printing and the Means of Fixing the same.* By Dr. Robert Bourcart. *Monit. Sc.* (3), tome iv.

The essential quality demanded in colours for dyeing and printing is solidity, both as regards lukewarm or boiling soap water, and also with reference to light. Two main classes of colours can be distinguished, viz., mineral colours and organic colours. An intermediate class is formed by the so-called lakes, these being a kind of coloured salts formed by the combination of metallic

or earthy oxides with organic substances, which are frequently colourless. Mineral colours may be classed in two groups: (1) Those produced by chemical reactions in the fibre; (2) those used ready made, and fixed with glutinous substances like albumen. Under the first heading we have chromium yellows and oranges, manganese browns, iron buffs, steam prussian blue, and some other less important colours. Under heading (2) come albumen colours, ultramarine, Guignet's green, chrome yellow, cinnabars, many browns and yellows, lamp black, and lastly metallic powders, such as gold, etc.

**MINERAL COLOURS PRODUCED IN THE FIBRE.**—*Colours Produced in the Wet Way, Chrome Yellow, and Orange:* If after producing the yellow chromate of lead by double decomposition the pieces are passed through boiling lime water a fine orange is obtained. When other processes precede treatment with lime water, then the lead salt should be printed in the state of a soluble salt on to the cloth prepared with  $\text{Na}_2\text{SO}_4$ , or else passing through baths of sulphate or phosphate of soda is the plan adopted. Sometimes  $\text{PbCl}_2$  is required to be formed, as, e.g., when working in combination with turkey red, and then a bath of bleaching powder is used to convert the nitrate of lead into  $\text{PbCl}_2$ . In the case of a resist under dyed indigo, the lead is precipitated in the state of hydrate. This hydrate is then converted by means of  $\text{HCl}$  and  $\text{K}_2\text{Cr}_2\text{O}_7$ . For the so-called "vert-solide" indigo is dyed on the chromate of lead yellow. For designs in several colours chromate of lead is used in conjunction with aniline black and all alizarine and aniline colours, both for dyeing on a mordant and for steam colours. However, passage through a boiling concentrated solution of  $\text{K}_2\text{Cr}_2\text{O}_7$  soon spoils delicate colours, and then ready-made chrome yellow is used and fixed with albumen. To prevent chrome yellows from blackening with sulphurous fumes, etc., thicken with gum senegal. Such yellows may be restored by being reoxidised with sodium carbonate and potassium ferricyanide, finishing up, if necessary, with another bath of bichromate. Discharges can be worked with alkalis on chrome yellow, e.g., by printing on  $\text{NaHO}$ —soluble sodium chromate being formed. However, we hardly think that this process, which is quoted from Persoz, is now in use. On the other hand, chrome orange is frequently converted into yellow, especially in connection with black work on vat blues with lead resists. In 1819 Professor Lassaigne showed how to fix lead chromate by precipitation in the tissue. It was first applied in 1820 by the firm N. Köchlin and Brothers; of Mulhouse, for discharges on dyed turkey reds. *Manganese Brown:* This colour is not obtained by double decomposition, but by the oxidation of a lower oxide. The prepare used is the chloride or sulphate of manganese, and after drying  $\text{NaHO}$  is used as the precipitant. A passage through dilute bleaching liquor or else hanging for a short time suffices to develop the brown colour required. This brown or "bistre" has the inconvenient property of not resisting the action of even very dilute acids. For obtaining discharges on the brown reducing agents, such as stannous chloride, are used, and then any capable of being fixed by tin can be worked in. The brown may be got of the required shade either in one operation or else, if dark, by passing through several baths of the manganese liquor. The latter method is much better, since then the shade obtained is more regular. If goods are not well washed in bleaching light spots are sometimes obtained in the brown, and this is due to the presence of traces of acid. A previous treatment with dilute  $\text{Na}_2\text{CO}_3$  before proceeding to form the brown will efficiently protect the latter from such defects. Hartmann, of Münster, near Colmar, first used this brown in 1815, and Mercer, in England, in 1830. Mercer also invented several new styles by combining manganese brown, chrome yellow, and vat blue. *Bismuth Brown:* According to Naquet a mixture of nitrate of bismuth and thiosulphate of sodium does not react as long as the salts are in solution, but when cloth is worked in these solutions and then dried, the brown sulphide of bismuth is obtained in twenty-four hours. This method has not yet come into general use. *Hydrate of Iron:* This is worked as in the case of manganese brown, ferrous sulphate and

caustic soda being used. The brown thus obtained is more or less yellow, and is known as "chamois" or "rouille." Resists and discharges can be worked by means of fixed organic acids or chloride of tin. Persoz gives a curious resist, consisting of green soap: this would probably form compounds preventing the hydrate from being precipitated in the fibre. *Soluble Prussian Blue:* In default of any other colour a Prussian blue discharge is used in combination with turkey red. Although turned brown by soap it resists washing with boiling water. The oxalic acid employed both dissolves the blue and liberates Cl in the bleach vat. D. Köchlin-Shouch first used prussian blue in this manner at Mulhouse in 1811. *Phosphate of Copper Green:* M. Camille Köchlin has invented a process for obtaining the above by printing a mixture of copper acetate, sodium phosphate, and ammonia. The green is brilliant, but not very dark. *Oxide of Chromium:* The greens obtained with this substance are more or less gray, and never very full. Attempts to develop Guignet's green on the fibre have not as yet succeeded, and oxide of chromium can well be replaced by albumen colours. When M. Camille Köchlin, in 1832, first applied it to textile colouring a fine green was got by adding arsenic acid. This is now legally forbidden, owing to the poisonous nature of the compound formed. When the new chrome mordant recommended by M. Horace Köchlin for dyeing "violet solide" is steamed a fine pale green is got on soaping. This mordant is a neutral ammonio-potassic chromate mixed with magnesium acetate.

**MINERAL COLOURS PRODUCED ON THE FIBRE BY STEAMING.**—*Prussian Blue:* This was much used formerly, but now comes in only for certain special styles. It is very fine, but does not stand soaping, and is produced by printing a mixture of potassium ferrocyanide and tartaric acid (or oxalic acid) and steaming. The addition of stannous chloride renders the colour much more brilliant, and acetate of chromium somewhat counteracts the injurious effect of soap. Prussian blue has the peculiar property of going pale when exposed to light, and being restored when kept in the dark. It is used for block-work with white discharges on turkey red; for greens it is combined with Persian berries, which is fixed by chromic acetate, and gives a brilliant yellow when tin is present as well. Prussian blue was discovered at the commencement of the eighteenth century by Diesbach, of Berlin, was first used in textile colouring in 1800 by Jean Michel Hausmann, of Lögelbach (Colmar), and as a steam colour was invented by Hindle, of Saddington, near Manchester. In 1820 the process was introduced to Messrs. Dollfus, Mieg, and Company, at Mulhouse, by Dollfus-Ausset, who brought it from England. *Red Prussiate for Darkening Steam Colours:* By means of this salt a darker shade can be given to certain steam colours, such as chocolate, olives, violets, etc. It can be combined with cerulean green, with "violet solide" with alizarine violet, and in these cases acts as a mordant. With steam aniline black and ordinary aniline black it acts as an oxidising agent. *Steam Cadmium Yellow* was discovered by M. Schmidt, of Rouen. This colour is beautiful but expensive, and is irregular in the intensity of its shade. Its formation depends on the fact that nitrate of cadmium and sodium thiosulphate do not react in the cold, but give yellow cadmium sulphide on steaming. *Persulphocyanogen Yellow:* M. Schmidt treats sulphocyanides of potassium or aluminium as if for aniline black, and thus, on steaming, obtains "canarine." He obviates tendering due to HCl by developing his colour by oxidation with vanadium. Canarine is, moreover, an excellent fixing agent for aniline colours, as it has great affinity for these, and soaping becomes practicable. *Steam Chrome Yellow:* M. Jaquet, of Mulhouse, obtains this colour by steaming a mixture of citrate of lead with chromate of zinc and citrate of ammonia. M. Schmidt steams a mixture of barium chromate and lead acetate, but as the barium chromate is not in solution the action only takes place with difficulty. *Steam Manganese Brown* was discovered by Balauche, of Rouen, and obtained by steaming a mixture of potassium bichromate, manganese chloride, and sodium acetate. Probably potassium chloride and manganese

chlorate are formed. The chromic acid oxidises the Mn and is decomposed into chromic oxide. The HCl in combination with the Mn will displace the acetic acid of the sodium acetate.

#### MINERAL COLOURS FIXED BY COAGULATION:—

Albumen is almost the only coagulant employed, and occurs in commerce in two forms—blood albumen and egg albumen. Egg albumen is more expensive, but yields an almost colourless aqueous solution, whereas that got from blood is more of a brown colour, and cannot be used for delicate shades: thus ultramarine blue, chrome yellow, and the vermilions can only be thickened with egg albumen. Guignet's green and the various ferric oxides may be mixed with blood albumen, likewise the mixture of ultramarine and lamp-blacks or indigo, which is used for blueish grays and slates. Attempts to replace albumen by chrome gelatine or other substances capable of being coagulated by heat or certain drugs have all been more or less failures. In presence of moisture albumen becomes insoluble when heated above  $74^{\circ}\text{C}$ , but when dry can be heated more strongly, without losing its power of dissolving in water. Commercial albumen always contains from 15 to 17 per cent. of moisture. Albumen colours are steamed like other steam colours, and may be combined with these, but mixtures of the two varieties cannot by any means be made. Thus we may print ultramarine and steam alizarine violet in the same pattern, but their mixture would never produce a violet. In Alsace it seems that albumen colours have almost fallen into disuse owing to the fact that Mulhouse printers have at their disposal a large variety of brilliant and fast colours, and thus can avoid the trouble of trying to procure good albumen at a reasonable price. In England albumen colours are much used not only for discharges on vat blue, for which indeed they are as well in use in France, but also for steam colours. Much albumen can be saved by using suitable thickeners and adding certain salts, which much increase its coagulating power, e.g., sulphate of zinc. The addition of a small quantity of white arsenic,  $\text{As}_2\text{O}_3$ , will prevent putrefaction from taking place. Albumen colours are mostly strengthened with gum dragon (gum tragacanth), as it is transparent and not voluminous when dried on the cloth. Turpentine is of much use, as it prevents frothing, a defect inherent to all albumen colours. Albumen is also used for thickening colours intended for discharges on vat blue. The principle of this style depends on the fact that a mixture of dilute  $\text{H}_2\text{SO}_4$  and oxalic acid liberates chromic acid from potassium chromate, and at the same time coagulates albumen. Ultramarine cannot be used for semi-discharges, owing to its being too sensitive to acids. Albumen colours can resist soaping if not at a boil and of too long duration, but they are much damaged by friction, and hence should be soaped at full width, as is mostly done in England. Dollfus, Mieg, and Company first employed these colours in 1844, and also fixed ultramarine by means of the whites of fresh eggs. Already in 1820 Broquette and Blondin, of La Glacière, near Paris, fixed lapis-lazuli or natural ultramarine by means of albumen, and Gonin, of Rouen, used it about the same date for fixing lamp black. Albumen discharge colours are of more recent date, and were introduced by Camille Köchlin in 1875, being now largely employed. In 1876 M. Depierre devised a curious method of obtaining albumen discharges on vat blue. Potassium ferri-cyanide and sodium carbonate are steamed with albumen. The indigo is destroyed by the oxidising action of the ferri-cyanide in alkaline solution, and the albumen is simultaneously coagulated. This method is, however, we believe, not in use, and is merely given as a scientific curiosity. In time, perhaps, chemists will succeed in replacing egg albumen, and trials are being made to obtain colourless blood albumen. Although this has not yet been done completely, still certain makers have arrived at very satisfactory results. Several chemists are at present studying the manner of fixing colours by means of chrome gelatine, and the process used consists in preparing the cloth with a mixture of bichromate of potash and sodium thiosulphate, the colours being thickened with gelatine. Another substitute for albumen is lactarine, which is prepared from milk and is
